Contributors *xi*

## SECTION 1

### Introduction

- 1. History of pain in children** 3  
Anita M. Unruh and Patrick J. McGrath
- 2. Prevalence and distribution of pain in children** 12  
Bonnie J. Stevens and William T. Zempsky
- 3. Long-term effects of early pain and injury: animal models** 20  
Suellen M. Walker
- 4. Long-term effects of pain in children** 30  
Ruth E. Grunau
- 5. Prevention of the development and maintenance of paediatric chronic pain and disability** 39  
M. Gabrielle Pagé, Anna Huguet, and Joel Katz

## SECTION 2

### Biological basis of paediatric pain

- 6. Nociceptive signalling in the periphery and spinal cord** 53  
Suellen M. Walker and Mark L. Baccei
- 7. Neuroimmune interactions and pain during postnatal development** 65  
David Vega-Avelaira and Simon Beggs
- 8. Central nociceptive pathways and descending modulation** 74  
Maria Fitzgerald

## SECTION 3

### Social and psychological basis of paediatric pain

- 9. Psychological theories and biopsychosocial models in paediatric pain** 85  
Rebecca Pillai Riddell, Nicole M. Racine, Kenneth D. Craig, and Lauren Campbell
- 10. Cognitive styles and processes in paediatric pain** 95  
Liesbet Goubert and Laura E. Simons
- 11. Pain in cultural and communicative contexts** 102  
Ignasi Clemente
- 12. Families and pain** 111  
Kathryn A. Birnie, Katelynn E. Boerner, and Christine T. Chambers
- 13. Pain, social relationships, and school** 119  
Paula Forgeron and Sara King
- 14. The effects of sex and gender on child and adolescent pain** 127  
Erin C. Moon and Anita M. Unruh
- 15. Sleep and pain in children and adolescents** 135  
Bruce D. Dick, Penny Corkum, Manisha Witmans, and Christine T. Chambers

## SECTION 4

### Pain in specific populations and diseases

- 16. Pain in children with intellectual or developmental disabilities** 147  
John L. Belew, Chantel C. Barney, Scott A. Schwantes, Dick Tibboel, Abraham J. Valkenburg, and Frank J. Symons

- 17. Paediatric cancer pain** 157  
Jennifer Hickman, Jaya Varadarajan,  
and Steven J. Weisman
- 18. Pain management in major paediatric  
trauma and burns** 171  
Greta M. Palmer and Franz E. Babl
- 19. Needle procedures** 184  
Anna Taddio
- 20. Procedural sedation** 194  
Joseph P. Cravero
- 21. Neuropathic pain in children** 205  
Suellen M. Walker
- 22. Inflammatory arthritis and arthropathy** 215  
Peter Chira and Laura E. Schanberg
- 23. Chronic pain syndromes in childhood:  
one trunk, many branches** 228  
Neil L. Schechter
- 24. Non-inflammatory musculoskeletal pain** 237  
Jacqui Clinch
- 25. Pain in sickle cell disease** 248  
Carlton Dampier and Lamia Barakat
- 26. Pain and gastroenterological diseases** 257  
Akshay Batra, Amanda Bevan, and R. Mark Beattie
- 27. Postoperative pain management** 269  
Richard F. Howard
- 28. Pain in palliative care** 280  
Ross Drake and Renée McCulloch
- 29. Recurrent abdominal pain** 289  
Jennifer Verrill Schurman, Amanda Drews Deacy,  
and Craig A. Friesen
- 30. Chronic pelvic pain in children  
and adolescents** 298  
Susan L. Sager and Marc R. Laufer
- 31. Headaches** 307  
Andrew D. Hershey
- 32. Persisting pain in childhood medical illness** 319  
Martha Mherekumombe and John J. Collins
- 33. Common pain problems in the  
outpatient setting** 328  
F. Ralph Berberich and Neil L. Schechter
- 34. Effective management of children's pain and  
anxiety in the emergency department** 338  
Robert M. (Bo) Kennedy

## SECTION 5

### Measurement of pain

- 35. Neonatal and infant pain assessment** 353  
Grace Y. Lee and Bonnie J. Stevens
- 36. Self-report: the primary source in  
assessment after infancy** 370  
Carl L. von Baeyer
- 37. Behavioural measures of pain** 379  
Jill MacLaren Chorney and C. Meghan McMurtry
- 38. Biomarkers of pain: physiological indices of  
pain reactivity in infants and children** 391  
Susanne Brummelte, Tim F. Oberlander,  
and Kenneth D. Craig
- 39. The neurophysiological evaluation of  
nociceptive responses in neonates** 401  
Ravi Poorun and Rebecca Slater
- 40. Sensory processing and neurophysiological  
evaluation in children** 407  
Christiane Hermann
- 41. Measurement of health-related quality  
of life and physical function** 417  
See Wan Tham, Anna C. Wilson, and Tonya M. Palermo

## SECTION 6

### Pharmacological interventions

- 42. Principles of pain pharmacology  
in paediatrics** 429  
Kim Chau and Gideon Koren
- 43. The non-steroidal anti-inflammatory  
drugs and acetaminophen** 436  
Brian J. Anderson
- 44. Developmental pharmacology of opioids** 449  
Gareth J. Hathway
- 45. Opioids in clinical practice** 457  
Scott A. Strassels
- 46. Interventional pain management  
techniques for chronic pain** 474  
Navil F. Sethna, Pradeep Dinakar, and Karen R. Boretsky
- 47. Topical anaesthetics and analgesics** 486  
William T. Zempsky
- 48. Drugs for neuropathic pain** 495  
Sachin Rastogi and Fiona Campbell

**49. Sucrose and sweet taste 508**

Denise Harrison, Vanessa C. Z. Anseloni,  
Janet Yamada, and Mariana Bueno

**SECTION 7****Psychosocial interventions****50. Cognitive-behavioural interventions 519**

Deirdre E. Logan, Rachael M. Coakley,  
and Brittany N. Barber Garcia

**51. Operant treatment 531**

Keith J. Slifer, Adrianna Amari, and  
Cynthia Maynard Ward

**52. Child life interventions in paediatric pain 543**

Chantal K. LeBlanc and Christine T. Chambers

**53. Procedural pain distraction 553**

Lindsey L. Cohen, Laura A. Cousins, and Sarah R. Martin

**54. Hypnosis and relaxation 560**

Christina Liossi, Leora Kuttner, Chantal  
Wood, and Lonnie K. Zeltzer

**55. New information and communication technologies for pain 569**

Jennifer Stinson and Lindsay Jibb

**SECTION 8****Physical interventions****56. Physical therapy interventions for pain in childhood and adolescence 581**

Susan M. Tupper, Mary S. Swiggum, Deborah  
O'Rourke, and Michael L. Sangster

**57. Occupational therapy 590**

Liisa Holsti, Catherine L. Backman, and Joyce M. Engel

**58. Mother care for procedural pain in infants 600**

Celeste Johnston and Marsha Campbell-Yeo

**SECTION 9****Special topics****59. Complementary drugs—herbs, vitamins, and dietary supplements for pain and symptom management 613**

Joy A. Weydert

**60. Complementary therapy in paediatric pain 623**

Lonnie K. Zeltzer

**61. Theory-informed approaches to translating pain evidence into practice 633**

Janet Yamada and Alison M. Hutchinson

**62. Organizational systems in paediatric pain 642**

Mark Embrett and Norman Buckley

**63. Education for paediatric pain 653**

Alison Twycross and Susan O'Conner-Von

**64. The ethics of pain control in infants and children 661**

Gary A. Walco and Maureen C. Kelley

**65. Sociodemographic disparities in paediatric pain management: relationships and predictors 669**

Miriam O. Ezenwa and Anna Huguet

**Index 677**

# Abbreviations

ACC	anterior cingulate cortex	CT	computed tomography <i>or</i> complementary therapy
ACT	acceptance and commitment therapy	CTTH	chronic tension-type headache
ADR	adverse drug reaction	CYP	cytochrome P450
AIDS	acquired immunodeficiency syndrome	DD	developmental disabilities
ALL	acute lymphoblastic leukaemia	DEX	dexmedetomidine
ANS	autonomic nervous system	DIP	diffuse idiopathic pain
AOE	acute otitis externa	DRG	dorsal root ganglion
AOM	acute otitis media	DTI	diffusion tensor imaging
APS	acute pain service	E	embryonic day
ART	antiretroviral therapy	ED	emergency department
ASA	American Society of Anesthesiologists	ECG	electrocardiography
BART	biofeedback-assisted relaxation training	EEG	electroencephalography
BBB	blood–brain barrier	ELGA	extremely low gestational age
BDNF	brain-derived neurotrophic factor	EM	erythromelalgia
BOLD	blood oxygen level-dependent	EMG	electromyography
ca	corrected age	ERP	event-related potential
CAM	complementary and alternative medicine	FAP	functional abdominal pain
CAMPIS	Child Adult Medical Procedure Interaction Scale	fcMRI	functional connectivity magnetic resonance imaging
CARRA	Childhood Arthritis and Rheumatology Research Alliance	FD	functional dyspepsia
CBT	cognitive-behaviour therapy	FDA	Food and Drug Administration
CBT-I	cognitive-behavioural therapy for insomnia	FDI	Functional Disability Inventory
CCBT	contextual cognitive-behavioural therapy	FGID	functional gastrointestinal disorders
CD	Crohn's disease	FLACC	Face, Legs, Activity, Cry, and Consolability scale
CFA	complete Freund's adjuvant	FM	fibromyalgia
CFCS	Child Facial Coding System	fMRI	functional magnetic resonance imaging
CHEOPS	Children's Hospital of Eastern Ontario Pain Scale	GA	gestational age
CHQ	Child Health Questionnaire	GBS	Guillain–Barré syndrome
CI	confidence interval	GCS	Glasgow coma scale
CIBP	cancer-induced bone pain	GI	gastrointestinal
CIHR	Canadian Institutes of Health Research	GORD	gastro-oesophageal reflux disease
CIN	chemotherapy-induced neuropathy	GVHD	graft-versus-host disease
CMV	cytomegalovirus	GW	gestational weeks
CNS	central nervous system	h	hour/s
CO <sub>2</sub>	carbon dioxide	HIV	human immunodeficiency virus
COMT	catecholamine-O-methyltransferase	HL	heel lance
COPM	Canadian Occupational Performance Measure	HPA	hypothalamic–pituitary–adrenal
COX	cyclooxygenase	HR	heart rate
CP	cerebral palsy <i>or</i> chronic prostatitis	HRQOL	health-related quality of life
CRPS	complex regional pain syndrome	HRV	heart rate variability
CSF	cerebrospinal fluid	IASP	International Association for the Study of Pain

IBD	inflammatory bowel disease	PARiHS	Promoting Action on Research Implementation in Health Services
IC	interstitial cystitis	PBn	parabrachial area
ICF	International Classification of Functioning, Disability and Health	PBRs	Procedure Behavioural Rating Scale
ICF-CY	International Classification Framework for Children and Youth	PBS	painful bladder syndrome
ICT	information and communication technologies	PCA	patient-controlled analgesia
ICU	intensive care unit	PedMiDAS	paediatric Migraine Disability Assessment
ID	intellectual disabilities	PedQL	Pediatric Quality of Life Inventory
ifn	interferon	PEPD	paroxysmal extreme pain disorder
IM	intramuscular	PET	positron emission tomography
IMg <sup>2+</sup>	ionized magnesium	P-gp	P-glycoprotein
INF	intranasal fentanyl	PHN	postherpetic neuralgia
INF	intranasal	PID	pelvic inflammatory disease
IPM	interventional pain management	PMP	prescription monitoring programme
IV	intravenous	PNA	postnatal age
JIA	juvenile idiopathic arthritis	PNCA	parent/nurse-controlled analgesia
KT	knowledge translation	PNI	peripheral nerve injury
LA	local anaesthesia	PO	per os (orally)
LC	locus coeruleus	POTS	postural orthostatic tachycardia syndrome
LCT	limited attentional capacity theory	PPC	Paediatric Pain Centre
LET	lidocaine-epinephrine-tetracaine	PPI	proton pump inhibitor
LPS	lipopolysaccharide	PPPM	Parents' Postoperative Pain Measure
LTP	long-term potentiation	PROMIS	Patient Reported Outcomes Measurement Information System
m-health	mobile-health	PSA	procedural sedation and analgesia
min	minute/s	PT	physical therapist
MIDAS	Migraine Disability Assessment	QST	quantitative sensory testing
MPC	multidisciplinary pain care	RAP	recurrent abdominal pain
mPFC	medial prefrontal cortex	RBC	red blood cell
MRI	magnetic resonance imaging	RCT	randomized controlled trial
MRT	multiple attentional resource theory	RVM	rostroventral medulla
MS	multiple sclerosis	S1	primary somatosensory cortex
N <sub>2</sub> O	nitrous oxide	S2	secondary somatosensory cortex
NAA	N-acetylaspartate	SC	subcutaneous
NCCAM	National Center on Complementary and Alternative Medicine	SCD	sickle cell disease
NCCN	National Comprehensive Cancer Network	SCM	social communication model
NCCPC	Non-communicating Children's Pain Checklist	SD	standard deviation
NG	nasogastric	SDH	superficial dorsal horn
NICE	National Institute for Health and Clinical Excellence	sec	second/s
NICU	neonatal intensive care unit	SES	socioeconomic status
NIH	National Institutes of Health	SIB	self-injurious behaviour
NIRS	near-infrared spectroscopy	SSNRI	selective serotonin and noradrenaline reuptake inhibitor
NMDA	N-methyl-D-aspartate	SSRI	selective serotonin re-uptake inhibitor
NNS	non-nutritive sucking	STT	spinothalamic tract
NNT	number needed to treat	TCA	tricyclic antidepressant
NP	neuropathic pain	TCM	traditional Chinese medicine
NRS	numerical rating scale	TDM	therapeutic drug monitoring
NS	nociceptive specific	UC	ulcerative colitis
NSAID	non-steroidal anti-inflammatory drug	UGT	uridine diphosphate glucuronosyltransferase
OIH	opioid-induced hypersensitivity	VAS	visual analogue scale
OMRU	Ottawa Model of Research Use	VNS	verbal numeric scale
OR	odds ratio	VPL	ventroposterolateral nucleus
OSBD	Observation Scale of Behavioural Distress	VPn	ventroposterior nucleus
P	postnatal day	WDR	wide dynamic range
PACU	post-anaesthesia care unit	WHO	World Health Organization
PADS	pain-associated disability syndrome		
PAG	periaqueductal grey

# CHAPTER 1

## History of pain in children

Anita M. Unruh and Patrick J. McGrath

### Summary

The problem of pain has likely concerned humankind from the beginning as pain is a compelling call for attention and a signal to escape from its source. Early efforts to understand pain, and its origins, features, and treatment reflected the duality between spiritual conceptualizations of pain and physiological explanations depending on the predominance of such views in a given culture in any given historical period (McGrath and Unruh, 1987). In the absence of physiological or behavioural explanations to explain persistent pain without obvious injury, when spiritual perspectives dominated, prayer, amulets, supplication, and religious rites dominated approaches to pain treatment. Herbal remedies were often part of such strategies and might themselves have had potent properties (Unruh, 1992, 2007). In ancient writings about pain and disease, treatments for children were often given alongside discussions about the health issues of women. In this chapter, we trace early approaches to pain in children to the modern era highlighting points of transition and improvements in paediatric pain management.

### A brief early history from ancient times to the mid nineteenth century

The earliest medical writings about the pain and diseases of children do not provide much information about symptoms of pain and disease in children but they do illustrate an understanding that children could not be treated medically as if they were adults. For example, the Atharva Veda of India (1500–800 BCE) provided paediatric incantations for headache, earache, and musculoskeletal pains (Garrison, 1923). The Susruta Samhita of India (second century BCE) gave dosages of drugs and herbal remedies for children separately from adults and advised administering them with milk, clarified butter, or in a plaster spread on the breasts of the nurse (Garrison, 1923). Hippocrates (about 460–357 BCE), Celsus (25 BCE–50 CE), Soranus (second century CE), Galen (130–200 CE), Oribasius (325–403 CE), Aurelianus (fifth century CE), Aetius (sixth century CE), and Aegineta (seventh century CE) all contributed to treatment of disease in infancy and childhood in their time period and beyond, in Greece and Rome, and in the Arab world. The Hippocratic writings of the fifth and fourth centuries BCE described constitutional differences between adults and children, and gave different doses of herbal remedies and means of administration

(Garrison, 1923; Still, 1931). Crying, restlessness, and sleeplessness were regarded as the primary symptoms of a child's pain and distress (Unruh, 1992).

One of the most reported pains of childhood prior to the eighteenth and nineteenth centuries was teething pain. The treatments for teething pain (Table 1.1) are fascinating to the modern reader and illustrate the underlying concern with which a child-specific pain was regarded throughout those centuries, and the ways in which remedies were passed down and modified over time. It was not uncommon for children to die in infancy and childhood when they were teething though illness and death were likely due to issues other than teething (McGrath and Unruh, 1987).

Determining whether a child was in pain was a challenge and not surprisingly generally determined by appeals to observation of changes in the child's behaviour. Aurelianus (fifth century CE) illustrates the emphasis on a child's behaviour as an indicator of pain:

The child groans in its sleep, rolls about, gnashes its teeth, tends to lie prone, cries out suddenly, or falls silent, is seized with convulsions, sometimes becomes somnolent, the face becomes emaciated and loses its colour; the child gets cold and answers questions with difficulty; sometimes throws itself about with outstretched hands, working itself into perspiration. (Quoted in Garrison, 1923, p. 47)

Though changes in general behaviour were important, crying was usually regarded as the chief indicator of a child's pain. Some physicians, such as Omnibonus Ferrarius (1577) (an Italian physician), (Still 1931), and Starr (1895) and Holt (1897) (both American physicians), believed that children only cried if there was a reason associated with distress. Both Starr (1895) and Holt (1897, 1908) associated different features of cries with specific illnesses and severity of pain. For example, a sudden, very loud and paroxysmal shriek was described as hydrencephalic cry associated with headache (Starr, 1895, p. 6). Holt (1897) described acute pain as having a sharp and piercing cry that was usually accompanied by contracting facial features and drawing up the legs and sometimes falling into an exhausted sleep. He ascribed these pains to earache and colic. Starr (1895) may have been the first physician to describe facial expression of pain. He also used these features to identify the source of pain:

The picture (of a healthy child) is altered by the onset of any illness, the change being in proportion to the severity of the attack. An expression of anxiety or suffering appears, or the features become pinched and the lines are seen about the eyes and mouth. Pain most of all sets its

**Table 1.1** Historical treatments of children's teething pain

Source	Treatments
Soranus, 2nd century CE	'Before teething, the gums should be gently rubbed with oil or fats, and the child may be permitted to suck fat bacon without swallowing, but this should cease when the teeth appear. The gums should not be irritated by butter or acid substances, and if there is much inflammation, poulticing, and sponging are recommended' (quoted in Garrison, 1923, p. 46)
Oribasious, 325–403 CE	'If they are in pain, smear [the gums] with dog's milk or with hare's brain; this works also if eaten. But if a tooth is coming through with difficulty, smear cyperus with butter and oil-of-lilies over the part where it is erupting' (quoted in Still, 1931, p. 38)
Aetious, 6th century CE	'He advises the root of colocynth, hung on the child in a gold or silver case, or brambleroot, or the tooth of a viper, especially of a male viper, set in gold, or a green jasper suspended on the neck so as to hang down over the stomach' (quoted in Still, 1931, p. 40)
Rhazes, 859–932 CE	'And the treatment of it, when the gum is swollen, is that the gum should be rubbed a little with the finger, and afterwards with oil and hen's fat or hare's brain or dog's milk; and apply to the child's head water in which there have been boiled camomile and dill, and put plasters which have a dispersing effect on his jaws; and if the pain in the part increases after this, take butter and oil of laurels, mix together and apply over the part; or take cow's butter and marrow from the thigh, and apply; and if the points of the teeth have appeared, put over the whole head and neck clean wool, and let some tepid water be sprinkled on the wool each day' (quoted in Still 1931, pp. 46–47)
Avicenna, 980–1036 CE	'For burning pain in the gums apply oil and wax as an epitheme or use salted flesh which is a little "high"' (quoted in Gruner, 1930, p. 372)
Phaer, 1546 CE	'There be divers things that are good to procure as easy breeding of teeth, among them the chiefest is to anoint the gummes with the braynes of an hare nyxte with as much capons grece and hony, or any of these thynges alone is exceedynge good to supple the gummes and the synewes ... And whan the payne is greatte and intolerable with apostema or inflammation of the gummes, it is good to make an ointment of oile of roses with the juyce of morelle otherwise called nightshade, and in lack of it annoint the jawes within with a little fresshe butter and honye' (quoted in Still, 1931, p. 121)
Sainte-Marthe, 1569 CE	'Hare's brain, honey and red coral ring as amulet' (cited in Ruhrah, 1925)
Ferrarius, 1577 CE	'A dead man's tooth in the opinion of some, through some particular virtue when hung on the neck of an infant, soothes and disperses the pain of teething' (quoted in Still, 1931, p. 156)
Primerose, 1659 CE	'Tooth of a dog, wolf or male viper hung around the neck to ease teething pain' (cited in Still, 1931)

mark upon the countenance, and by noting the features affected it is often possible to fix the seat of serious disease. Thus, contraction of the brow denotes pain in the head; sharpness of the nostrils, pain in the chest; and a drawing up of the upper lip, pain in the abdomen. (Starr 1895, pp. 3–4)

At least two surgical procedures, trepanation (a hole bored in the skull to treat headaches, mental illness, and convulsions) and circumcision, were performed on children in the ancient world throughout history (Liskowski, 1967). Other paediatric surgeries included repair of inguinal hernia, and harelip, tonsillectomy, and severance of the frenulum of the tongue (Mettler and Mettler, 1947). Opium, hyoscyamus, mandragora, and wine were used for pain relief during surgery (e.g. Celsus 25 BCE–50 CE and Avicenna 980–1036 CE) (McGrath and Unruh, 1987; Mettler and Mettler, 1947) but physical restraint was the more common approach. For children, surgical procedures were exceedingly painful and difficult for the patient and physician. Celsus' advice for the surgeon was:

A chirurgien must have a strong, stable and intrepid hand and a mind resolute and merciless; so that to heal him that he taketh in hand, he be not moved to make more haste than the thing requireth, or to cut less than is needful, but which doth all things as if he were nothing affected with their cries. (Quoted in Griffith, 1951, p. 127)

Children suffered when they had pain throughout this period (Newton, 2011). Although there is evidence that children were also cared about, and efforts made to manage their pain (McGrath and Unruh, 1987), it was anaesthesia that offered the first prospect of significant pain relief.

Early modern history starts with anaesthesia 1840–1950

The experience of pain was transformed by the development of anaesthesia in the nineteenth century. In 1842, Crawford Long used diethyl ether to excise a cyst from a patient's neck (Long, 1849), and then in 1846 William Morton gave a public demonstration of the use of ether for a dental procedure (Costarino and Downes, 2005). Children were involved in the earliest clinical applications of anaesthesia; the third patient who received ether from Long was an 8-year-old boy whose diseased toe was amputated on 8 July 1842 (Stewart, 1989). John Snow (1885), Queen Victoria's anaesthetist, started using diethyl ether for children in 1847 and 10 years later reported on his use of chloroform with several hundred children, 186 of whom were infants (Costarino and Downes, 2005). While children commonly received anaesthesia for surgery from the beginning, they were also perceived to have more problems associated with anaesthesia such as nausea and vomiting, hypotension, respiratory depression, and cardiac arrest, especially with chloroform (Costarino and Downes, 2005). The first recorded deaths due to anaesthesia occurred in children (Stewart, 1989). Some invasive procedures were considered so short or so minor that anaesthesia was thought not to be required. For example, Wharton (1895) did not consider a tracheotomy painful if there was marked dyspnoea, and thought that it was only the first incision that was painful. Similarly, Casselberry (1895) did not feel an anaesthetic was needed for a tonsillectomy because of the brevity of the procedure unless the adenoids were also to be removed. Pernick (1985) noted

that procedures other than amputations of limbs were often considered minor.

In 1898, August Bier used cocaine to induce spinal anaesthesia in six patients, two of whom were children but he did not perceive spinal anaesthesia to be beneficial (Brown, 2012). By 1910, three papers had been published in *The Lancet* each referring to 100 or more paediatric cases in which spinal anaesthetics, rather than general anaesthesia, were used (Gray, 1909a, 1909b, 1910). Regional anaesthesia may have evolved due to the associated risks of general anesthesia in children but as paediatric general anaesthesia improved in the 1930s to 1950s, regional anaesthetics were less frequently used and are still not widespread (Brown, 2012).

The advancement of paediatric pain management during surgery was dependent on the development of anaesthetic agents, management of negative side effects of these agents, adequate training of physicians in the use of anaesthetics, and development of anaesthetic equipment that was appropriate for use with infants and children. Rendell-Baker (1992) described the historical evolution of paediatric anaesthesia equipment as having different developmental phases including: use of open drop mask for chloroform; introduction of tracheal intubation (beginning in 1909); development of various breathing systems (Magill's breathing system, Mapleson E T-piece breathing system, paediatric laryngoscopes, paediatric tracheal tubes, the Crowe-Davis mouth gag, the laryngeal mask airway); design of cyclopropane and carbon dioxide absorption systems (non-rebreathing valves); the T-piece system; specialization of paediatric anaesthesia as a medical subspecialty; use of halothane and low-dead space paediatric face masks and related equipment; introduction of standard breathing systems; and use of constant positive airway pressure and intermittent mandatory ventilation. The first paediatric anaesthetic textbook, *Anaesthesia in Children* by Langton Hewer, appeared in 1923, with a second textbook, Leigh and Belton's *Pediatric Anesthesia*, available in 1948.

The primary advantage of anaesthesia was the relief of pain with the secondary effect of permitting increasingly more complex (and invasive) surgical procedures. At the outset, in its earliest period, the beneficiaries were most likely to be women, white people, young children, and people from upper and middle classes (Jackson Rees, 1991). Children were viewed as more sensitive to pain, and more difficult to control if they were anxious and fearful about the procedure (Pernick, 1985). But with respect to the pain experience of infants, there was disagreement about the best approach. On the one hand, there were those physicians, like Eliza Thomas (1849), who regarded infants as hypersensitive to pain (cited in Pernick, 1985). There were other physicians whose views resonated with Henry Bigelow (1848) who wrote: 'The fact that it [infant] has neither the anticipation nor the remembrance of suffering, however severe, seems to render this stage of narcoticism [full anaesthesia] unnecessary' (quoted in Pernick 1985, p. 172). Stewart (1989) wrote that infants were considered ideal patients for surgery by some because they were considered relatively insensitive to pain, unable to appreciate it, and even capable of sleeping through the surgery. In 1938, Thorek wrote: 'Often no anesthesia is required. A sucker consisting of a sponge dipped in some sugar will often suffice to calm a baby' (p. 2021).

This view of relative insensitivity to pain in infants seemed to be supported by studies that endeavoured to elicit pain. In 1917, Blanton reported on studies of the response of infants to procedures such

as blood draws, lancing of infections, and exposure to pin pricks during sleep. She observed crying and defensive escape behaviour but reported them as complex and advanced, reflexive and instinctive behaviours. In 1941, McGraw used pin pricks to examine the maturation of nerves in 75 children from infancy to 4 years. She maintained that the diffuse body movements of neonates with crying reflected a limited sensitivity to pain in the first 2 weeks of life and that it was unlikely for there to be any neural mediation above the thalamus.

But there continued to be opposing points of view. Charles Robson, anaesthetist at the Hospital for Sick Children in Toronto, perhaps the first paediatric anaesthesiologist (Mai and Yaster, 2011), vehemently rejected outright assumptions about infant insensitivity to pain:

First, it has been stated that infants under seven days of age do not require anesthetics for operations—that their association tracts for pain are not fully established and that minor operations may be carried out without any damaging effects on the infant. Personally I do not believe this and it is simply vivisection to operate on a conscious screaming wriggling infant without using a general or local anesthetic. (Robson, 1925, p. 235)

Robson used open-drop ether and cyclopropane along with tracheal intubation for infant anaesthesia (Mai and Yaster, 2011).

Views such as Robson's were probably in the minority. There is little discussion about pain in early textbooks about paediatric anaesthesia, not even with respect to neonates. Smith's *The Physiology of the Newborn Infant* (1945) did not mention pain at all. Leight and Belton (1948) made only one substantive comment about pain:

Newborn infants are not as sensitive to pain and some degree of analgesia is present without anesthetic. Most infants, however, do have some pain sensation even at birth and one cannot rely on the old adage that there is no pain sensation for the first three weeks of life. It is nearer the truth to say that sensitivity to pain is decreased. Since there is some basic analgesia, very low concentrations of anesthetic agent will produce complete analgesia. (p. 30)

By the mid twentieth century, the prevailing view, that infants had reduced sensitivity to pain, provided an accepted position for the use of minimal anaesthesia for surgery on infants. In the 1950s, Gordon Jackson Rees in Liverpool, England, introduced an approach that came to be known as the Liverpool technique. He modified a part of the paediatric anaesthetic equipment to permit better monitoring of respiratory movements of anaesthetized children and provide intermittent ventilation if needed (Costarino and Downes, 2005). He also introduced curare and other relaxants into practice and nitrous oxide and oxygen anaesthesia without ether (Jackson Rees, 1960). In his 1950 discussion about anaesthesia in the newborn, Jackson Rees argued that the newborn was substantially different from an adult in neuromuscular structure and physiology (mechanical differences, sensitivity of the respiratory system, muscle tone). While he supported using muscle relaxants to reduce the amount of anaesthetic agents, he believed that control of respiration was possible with light anaesthesia without muscle relaxants for infants because of these structural and physiological differences. He believed the 'operative risk' to full-term infants was slight because fetal cord blood levels of corticosteroids at birth paralleled those of the mother, hence surgical trauma was less at birth but then increased rapidly during the first week of life. The optimum operative period was regarded by Jackson Rees (1950) to be the first 24 hours of life. Jackson Rees (1950) noted that Leigh and Belton

(1948) had suggested premedication with morphine for very young infants with morphine but believed it was generally not necessary:

This treatment appears to facilitate the smooth maintenance of anesthesia, and would seem to be desirable if respiration is not to be aided or controlled. It does, however, make the induction of anesthesia by inhalation agents—a tedious process at best—a very prolonged procedure. (p. 1421)

In his 1960 paper, Jackson Rees discussed in some detail the anaesthetic complications of paediatric anaesthesia such as the tendency for infants under 6 months to become hypothermic in response to anaesthesia whereas older infants became hyperthermic. Hypothermia was more readily managed but hyperthermia sometimes led to convulsions and death. Ether anaesthesia and atropine premedication contributed to this risk. In summarizing his views, Jackson Rees (1960) wrote:

The respiratory deficiencies of the infant during early life and the hazards of hyperthermia in older children suggest that controlled ventilation during the maintenance of anaesthesia has special advantages. It should be regarded as an essential part of the technique for prolonged operations, and is highly desirable for shorter procedures. Anaesthesia can be maintained at very light levels with nitrous oxide-oxygen and a relaxant drug, with the result that recovery is rapid.... There are, therefore, cogent practical and theoretical reasons for maintaining anaesthesia with controlled ventilation, a relaxant drug, nitrous oxide and oxygen. (p. 138–139)

Although Jackson Rees is said to have introduced nitrous oxide and oxygen anaesthesia without ether, it had already been in use for some years in the US by some physicians. Mary Botsford in San Francisco (1935) reported using this preparation over a 2-year period for children from 1 month to 4 years of age for procedures of 4 minutes to 1 hour and 40 minutes. However, for the youngest infants, Botsford regarded ether as the anaesthetic of choice. Botsford also noted that by the 1930s, chloroform had been almost completely discontinued for infants and children because of deleterious effects on the liver, cardiac depression, and postoperative acidosis. In the discussion section of Botsford's paper, where responses were provided from colleagues, two writers, Weeks and Delprat, commented, 'We are glad to see that she still allows us to use ether in babies, even though she so strongly favours nitrous oxid[e] and oxygen'. Weeks and Delprat maintained that for abdominal surgery nitrous oxide and oxygen provided too little relaxation of the tissues, and they were prepared to risk a less safe anaesthetic (ether).

Nitrous oxide and oxygen anaesthesia with a muscle relaxant was considered for many years a light anaesthetic that was sufficient for many paediatric procedures. It appeared to reduce a number of surgical risks, especially for infants, based on the knowledge in this period of the physiology of infants and children. Although there were some efforts to understand the responses of the paediatric patient to surgical procedures, evidence of informed decision-making was typically on the basis of published clinical series. Such papers provided clinical information but very limited data about an infant's physiological stress response to invasive procedures. Paediatric pain research during this period was limited and focused on the first epidemiological studies and not clinical care.

## Scientific approaches to pain in children

The second half of the twentieth century can rightly be considered the modern era of paediatric pain research and management. Major

developments occurred that brought scientific thinking to the area and widespread realization in the health system that paediatric pain was an important issue. Development of the field of paediatric pain was, and continues to be, uneven. Even in developed countries, the provision of services is not at all uniform. In the developing world, paediatric pain research is just beginning (e.g. Forgeron et al., 2009). Advances in science have not always resulted in advances in implementation of care. There were significant landmark events that led to the modern era of paediatric pain.

Recurrent pain in children certainly was known and written about earlier (e.g. Matthews, 1938), but programmes of research about pain in children developed primarily in post-war Europe. The seminal work in headache was by Bo Vahlquist (Vahlquist, 1955; Vahlquist and Hackzell, 1949) and later by his protégé Bo Bille (1962) in Sweden. Vahlquist defined criteria for diagnosis of headache in children and presented clinical series and described common features. Bille's doctoral dissertation, published as a monograph in *Acta Paediatrica*, was a large-scale epidemiological study of the children of Uppsala. He described the prevalence and correlates of migraine and provided a more detailed set of lab studies and interviews with a subgroup of children who had pronounced migraine. Bille personally followed the group of 73 children with pronounced migraine for 40 years (Bille 1997). This work was foundational for all subsequent studies of migraine and other headaches in children and adolescents.

John Apley and colleague (Naish and Apley, 1951) in Bristol, England, published epidemiological research on recurrent limb pains demonstrating that about 4% of children had such pain. This paper was followed by his groundbreaking epidemiological and aetiological studies on recurrent abdominal pain (Apley, 1959). Apley found that recurrent abdominal pain was common, affecting 10.8% of children. Girls were more likely to have recurrent abdominal pain than boys. He linked recurrent abdominal pain to psychosocial problems and argued that overmedicalization of recurrent pain led to long-term consequences. Apley's studies still inform our understanding of recurrent limb and abdominal pain. While these studies on recurrent pains in children were well known in the paediatric literature, and stimulated clinical practice, they did not trigger much systematic research interest until the 1980s.

In 1965, Melzack and Wall introduced an imaginative and comprehensive theory, known as the gate control theory of pain, to account for horrific injuries that sometimes were not felt as pain, and minor injuries that were sometimes felt as severe pain. They used recently discovered physiological data and clinical data to suggest that a mechanism in the substantia gelatinosa of the dorsal horn of the spinal cord gated sensations of pain from pain receptors before they were interpreted or reacted to as pain. This theory changed how pain was conceptualized and united clinical observations with physiology. Although not specifically describing mechanisms of action for the role of attention, thoughts, and emotions in pain, Melzack and Wall included these phenomena by hypothesizing a central control trigger that could mediate specific central activities. The development of modern models of pain increased interest in pain research and in the integration of clinical observation with the biology of pain.

But drawing attention specifically to pain in children did not come easily. Interest was sporadic and research still almost nonexistent. Jo Eland was the first North American clinician scientist to bring pain in children to the forefront. In 1971, she was a faculty

member supervising students on a paediatric oncology unit in Omaha, Nebraska. Children were typically diagnosed late, received ineffective treatment, and died in pain with little pain relief. In her President's Message at the American Society of Pain Management Nurses in 2012, Eland said of this experience:

Watching so many children die in unrelieved pain caused me to begin reading everything I could about pain and soon found there was virtually nothing written about pediatric pain. The memories of so many children dying in unrelieved pain left a lasting impression that has never left me. (Reproduced with kind permission of Jo Eland)

Eland and Anderson (1977) noted that only 33 scientific articles had been published on pain in children by the mid 1970s and most of these papers were on paediatric recurrent pain. Their own important contribution to paediatric pain was a comparative chart review of the pain relief given to adults and children following similar surgical procedures. In the review of 25 children, aged 4–8 years, 21 children had been ordered analgesics but only 12 received any medication. Eighteen of the children were then matched with adults receiving similar surgery. The adult group were given 372 opioid analgesic doses and 299 non-opioid pain doses. There were methodological limitations to this review as a study: it was not experimentally well controlled, it used questionable matching, and did not measure pain. It is unknown whether the data from the adult sample came from a similar time period to that of the children or from the same institution. Nevertheless, the difference in the provision of pain relief between child and adult patients was startling and overwhelming in illustrating that children and adults were not treated similarly for pain. This study triggered two methodologically superior studies with similar though less extreme results. Beyer and colleagues (1983) compared 50 children with 50 adults on the postoperative analgesia they received following similar cardiac surgeries. The only patients who were not prescribed any analgesics at all were six children. Overall children received less than 50% of the analgesic doses given to adults. Schechter et al. (1986) reviewed charts for the postoperative analgesics received by 90 children and 90 adults who were randomly selected and matched for sex and diagnosis. Adults received an average of 2.2 doses of opioids narcotics per day, whereas children received half this amount. It is unknown whether the children in these studies were in more pain than adults, as pain was not measured. Nevertheless, these three studies critically established that children's pain was significantly undertreated in hospitals.

Along with these early studies which identified the problem of recurrent pains, abdominal pain, and headache in childhood, and undertreatment of postoperative pain in children, work was beginning to untangle the cry of infants, crying long being regarded as symptomatic of pain and distress in infants. In the 1960s, auditory and spectrographic cry analysis of infants was systematized by Ole Wasz-Höckert and colleagues in Finland (Wasz-Höckert et al., 1968). This work was sophisticated and well respected, and dealt with pain and other types of cries, but did not influence the investigation of pain outside of cry analysis.

The most seminal developments to draw attention to pain in infants and children were two events in the 1980s. The first was a series of studies by Kanwaljeet Singh Anand as a PhD student at Oxford University. With support from a Rhodes Scholarship and the John Radcliffe Hospital, Anand began one of the first research programmes on pain in neonates. Anand developed sophisticated

methods of measuring hormonal stress responses using very small samples of blood (Anand et al., 1985). He then demonstrated in clinical series and well-controlled, randomized trials, that term and preterm neonates mounted a major stress response following surgery for patent ductus repair (Anand and Hickey, 1987; Anand et al., 1987, 1988, 1990). These studies showed that neonates receiving minimal anaesthetic, the 'Liverpool' technique that had been standard care since the 1950s, compared to neonates receiving halothane anaesthesia, had significantly elevated levels of plasma epinephrine, norepinephrine, cortisol, glucagon, beta endorphins, and insulin, and as well as increased mortality in the postoperative period.

Anand's research was well received in the academic community. Anand won the 1986 Dr Michael Blacow prize for the best paper by a trainee at the annual meeting of the British Paediatric Society (Royal College of Paediatrics and Child Health, n. d.). For the public, the realization that infants were exposed to surgery with minimal anaesthesia came as a profound shock and was met with initial disbelief. In the media, Anand was viciously attacked in the *Daily Mail* (UK newspaper) in a story titled 'Pain killer shock in babies operation' (*Daily Mail*, 1987). Anand and colleagues were accused of experimenting on babies by withholding anaesthesia. The All Party Parliamentary Pro Life Group demanded that the General Medical Council investigate these experiments. Many distinguished medical scientists insisted that these studies were ethical, and methodologically rigorous challenges of then current standard of anaesthetic procedure for infants undergoing surgery, and would lead to better care. In 1988, Sir Bernard Braine, head of the All Party Group publicly apologized for his accusations (Anonymous, 1988).

The second seminal event was related to Anand's work but occurred in the US and was not research but one family's experience. Like Anand's research, the story of Jeffrey Lawson focused on neonatal anaesthesia and it too was debated in the public arena through the media. Jeffrey Lawson was born in February 1985, at 25–26 weeks gestational age, weighing 760 grams, and was admitted to the Washington National Children's Hospital for treatment of patent ductus arteriosus—a not uncommon problem in a premature infant. The ductus arteriosus is a blood vessel that permits blood to circulate through the baby's lungs before birth, closing a few days after birth. A patent ductus arteriosus leads to abnormal blood flow between the aorta and pulmonary artery, two major blood vessels that carry blood from the heart. After some medical attempts to correct this condition, Jeffrey Lawson underwent open heart surgery to correct this abnormality. His mother described Jeffrey's anaesthesia during the surgery in this way:

Jeffrey was awake through it all. The anesthesiologist paralyzed him with pavulon, a drug that left him unable to move, but totally conscious. When I questioned the anesthesiologist later she said Jeffrey was too sick to tolerate powerful anesthetics. Anyway, she said, it had never been demonstrated to her that premature babies feel pain. (Lawson, 1986, pp. 124–125)

Following surgery, Jeffrey went into shock, catabolized, and suffered heart, kidney, and liver failure. He died on 31 March 1985, 5 weeks following surgery. Ms Lawson contacted many professional and social service agencies and other individuals to support her belief that babies should receive pain control for surgical procedures before her story was picked up by the media.

In writing the story of Jeffrey Lawson for *The Washington Post*, Sandy Rovner quoted Willis McGill, Chair of Anesthesia at the

Children's Hospital National Medical Centre. Dr McGill asserted that there were risks with anaesthesia and that 'it doesn't do any good to have a dead patient who doesn't feel pain' (Rovner, 1986, p. 7). The article in *The Washington Post* triggered other coverage emphasizing that babies were undergoing surgery without anaesthesia. The American Society of Anaesthesiologists (1987) and the American Academy of Pediatrics (1987) asserted that anaesthesia should not be routinely withheld from neonates. In 1996, the American Pain Society established the Jeffrey Lawson Award for Advocacy in Children's Pain Relief to honour Jeffrey Lawson and the contribution of his mother to the advancement of pain in infants and children.

The Anand story in England and the Lawson case in the US were compelling. They were followed by a dramatic increase in professional and scientific interest in pain in children. Between 1981 and 1990, there were 2966 articles on paediatric pain with a striking increase occurring in the 1980s (Guardiola and Baños, 1993) and an upsurge in articles on pain in neonates (Baños et al., 2001). Books on some specific pains in childhood, such as Apley's book on abdominal pain (1959), had already appeared, but now, the first books covering the broad area of childhood pain were published (Table 1.2). Most of these books have been directed to health professionals but some focused on helping parents to manage their children's pain (Table 1.3).

**Table 1.2** Books for health professionals on pain in infants, children, or adolescents

Author(s)	Title	Year
Ross and Ross	<i>Childhood pain: Current issues, research and treatment</i>	1988
McGrath	<i>Pain in children: Nature, assessment, and treatment</i>	1989
Schechter and Berde	<i>Pain in infants, children and adolescents</i>	1993

Author(s)	Title	Year
Finley and Turner	<i>Making cancer less painful: A handbook for parents</i>	1992
McGrath et al.	<i>Pain, pain go away: Helping children with pain</i>	1994
Kuttner	<i>A child in pain: How to help, What to do</i>	1997
Krane and Sinberg	<i>Relieve your child's chronic pain: A doctor's program for easing headaches, abdominal pain, fibromyalgia, juvenile rheumatoid arthritis, and more</i>	2005
Zeltzer and Schlank	<i>Conquering your child's chronic pain: A pediatrician's guide to reclaiming a normal childhood</i>	2005

The International Association for the Study of Pain established a Special Interest Group on Pain in Childhood (<<http://www.child-pain.org>>) in the 1980s. One of its activities is the International Symposium on Pediatric Pain (<<http://childpain.org/ispp.shtml>>), the first was held in Seattle in 1988. The PEDIATRIC-PAIN electronic discussion list began in the 1990s (PEDIATRIC-PAIN@lists.dal.ca>). At present it has over 800 members and remains an active discussion forum. The Pediatric Pain Letter (<<http://www.childpain.org.ppl>>) began in 1996. The International Pediatric Pain Forum is another paediatric pain meeting. It is held every 2–3 years on a focused theme (<<http://pediatric-pain.ca/content/IFPP>>).

It is difficult to know how much of this increased attention on children's pain was due to the public attention and debate that surrounded the research of Anand, or the tragic story of Jeffrey Lawson. The research in this area was gaining sufficient momentum for the first paediatric pain books to appear and the first paediatric pain conference to be held. Nevertheless, there is no doubt that these events highlighted in undeniable ways the assumptions and misconceptions that prevailed and persisted in children's pain, their serious potential for harm, and lent urgency to the need for change.

## The contributions of modern science to paediatric pain and the future

Science relies on assessment and measurement. Until the last three decades of the twentieth century, measurement of children's pain relied on unstandardized, largely descriptive approaches to determine whether a child was in pain. Empirical research confirmed that an infant's cry due to distress had specific spectrographic properties (Wasz-Höckert et al., 1968), and that cries due to pain, hunger, and fear could be distinguished from each other by trained observers and by spectrographic analysis (Anand and Hickey, 1987). Moreover, there are behavioural and spectrographic differences in the pain cries of healthy full-term neonates, preterm neonates, and neonates with neurological impairments (Anand and Hickey, 1987). Facial characteristics of a child in pain, the features noted by Starr in 1895 with respect to the brow, the nostrils, and the upper lip, are characteristics of the pain face now captured in paediatric pain measures such as the Neonatal Facial Action Coding System (Grunau and Craig, 1987). In the 1970s and 1980s, the first self-report measures of pain were developed and later, self-report measures based on facial characteristics—e.g. the Faces Pain Scale (Bieri et al., 1990) and the Faces Pain Scale—Revised (Hicks et al., 2001). In addition, observational measures of children's pain behaviour, particularly in the postoperative context, were constructed and validated. Measures were also developed for children with developmental disabilities and for pain in infants. Such tools provided the capacity to measure the effectiveness of pain intervention for infants, children, and adolescents. Much of this work is reviewed in the books mentioned in Table 1.2 and in Section 5 of this book.

In addition to pain measurement, attention was drawn to special areas of pain in infants, children, and adolescents and its treatment such as in burns, procedural pain, cancer pain, arthritis, and so on. There was greater appreciation of the immediate and long-term consequences of pain in childhood due to physical and sexual abuse. In the last 10 years there has been a more solid focus on the social and cultural context of children's pain and the role of parents in children's learning about pain. A great deal of work has focused

on children's pain in the Western world. Recently, researchers have come to recognize that the pain of children in underdeveloped countries is even more greatly challenged by the lack of education about child pain and limited or no access to appropriate pain management.

Only fools try to predict the future but some emerging trends are evident. There will certainly be greater advances in our understanding of the biomedical, social, cultural, clinical, and health systems science of pain in children. The yet to be resolved problem of insufficient access to scientifically demonstrated treatments for pain for infants, children, and adolescents is slowly being recognized, and is leading to new ways of developing interventions such as Web-based alternatives (see Stinson and Jibb, Chapter 55, this volume). The need for personalized approaches to care is being understood. But will all of our progress in science make a difference in practice? Will the financial crisis that is gripping many parts of the world lead to less care for the most vulnerable who have the least ability to demand better care? Will there be better solutions to the inadequate management of pain in children in all parts of the world? We need to consider and take responsibility for narrowing the gap between the generation of evidence and its application in the real world where pain occurs.

## Acknowledgements

McGrath's research is supported by grants from the Canadian Institutes of Health Research and his Canada Research Chair. This chapter is based on previous publications including McGrath (2011), McGrath and Unruh (1987), and (Unruh, 1992).

## CHAPTER 2

# Prevalence and distribution of pain in children

Bonnie J. Stevens and William T. Zempsky

### Introduction

There has been a paucity of studies that have attempted to determine the prevalence and distribution of pain (acute or chronic) in large groups of infants and children across multiple settings. Rather, there is a preponderance of single-site studies that report local prevalence and distribution of paediatric pain data. Although one could extrapolate these results to gain a broader sense of pain in children, this approach would garner only a general estimate at best. Furthermore, studies of pain prevalence vary as to the pain and prevalence definitions used, the reporting period (i.e. *point prevalence*, *period prevalence*), and stratification by duration of involvement, which makes comparison of findings challenging. In this chapter, definitions of prevalence and acute and chronic pain will be clarified and used to explore the prevalence and distribution of pain in hospitals and in community health care settings for infants and children. Recommendations for clinical practice and future research will be proposed.

### Definitions

*Prevalence* is the proportion of a population found to have a condition (typically a disease) and is determined by comparing the number of individuals with the condition with the total number of people studied. 'Point prevalence' is the proportion of a population that has the condition at a specific point in time. 'Period prevalence' is the proportion of a population that has the condition at some time during a given period (e.g. neonatal period during the first year of life). Prevalence is different from incidence, which is a measure of *new* cases arising in a population over a given period.

*Acute pain* signals a specific nociceptive event, injury, or illness and is usually limited to a short period of time. Acute pain is frequently associated with sudden-onset, short, sharp, tissue-damaging procedures (e.g. heel lances, finger pricks, intravenous starts, intramuscular injections, lumbar punctures) for diagnostic or non-tissue-damaging procedures (e.g. suctioning) for therapeutic purposes. Acute pain typically subsides with effective management after the painful event (e.g. heel lance) or when the illness or injury resolves; however, it can be prolonged and reoccur in multiple episodes over time. *Acute prolonged pain* extends beyond that of the short-sharp, tissue damaging procedural pain but usually has

a predictable course that coincides with a 'usual' healing time and subsides within a few hours or days (e.g. postoperative pain).

*Chronic pain* is frequently defined as pain without apparent biological value that has persisted beyond the normal tissue healing time. Chronic pain promotes an extended and maladaptive stress response that includes neuroendocrine dysregulation, fatigue, dysphoria, myalgia and impaired psychological and social functioning. The temporal delineation of 'healing time' is frequently debated but is usually stated as somewhere between 3 and 6 months. The International Association for the Study of Pain (IASP) defines chronic pain as pain that lasts longer than 3 months (<<http://www.iasp-pain.org/Content/NavigationMenu/GeneralResourceLinks/PainDefinitions/>>). The temporal delineation presents additional dilemmas when considering prolonged pain in infants and young children and in those with disabilities who either are incapable of or may have difficulty in reporting their pain. For further discussion on assessment of pain in vulnerable populations, see Lee and Stevens (Chapter 35, this volume) and Below et al. (Chapter 16, this volume). Chronic pain can either be recurrent or persistent. *Recurrent pain* includes episodic acute pains such as headaches and stomach aches; more *persistent pain* is more enduring pains includes backaches.

### Pain in hospitalized infants and children

#### Acute pain

##### Neonates and infants

Acute pain during infancy was ignored until approximately three decades ago due to biases and misconceptions regarding the maturity of the infant's developing nervous system, their inability to verbally report pain, and their perceived inability to remember pain. Many infants endured frequent invasive medical procedures such as repetitive heel sticks and even surgery without benefit of anaesthesia or analgesia. More recently, these beliefs and misconceptions are rarely stated or acknowledged due to enhanced understanding of the developmental neurobiology of infant pain pathways and supraspinal processing. However, infants, and particularly hospitalized neonates, continue to be exposed to multiple painful procedures for diagnostic and treatment purposes and persistent, prolonged, or even chronic pain.

Several researchers have documented the incidence, prevalence, and frequency of procedural pain in infants hospitalized in the neonatal intensive care unit (NICU). Johnston and colleagues (2011) conducted a prospective observational study in 14 Canadian NICUs documenting both tissue-damaging (e.g. heel lance) and non-tissue-damaging (e.g. suctioning) procedures over a 1-week period. A total of 3508 tissue-damaging (mean = 5.8, standard deviation (SD) = 15) and 14 085 (mean = 25.6, SD = 15) non-tissue-damaging procedures were recorded for 582 infants. Twelve years earlier, Johnston and colleagues (1997) reported that the average number of painful procedures per infants was 14, similar to other prevalence surveys of infant procedural pain at the time (Anand and Selankio, 1996; Barker and Rutter, 1995; Fernandez and Rees, 1994; Porter et al., 1997; Simons et al., 2003).

In Johnston et al.'s 2011 study, the mean of 5.8 (SD 15, range 0–89) tissue-damaging procedures per infant appears to be a significant improvement. In 1996, no infants received pharmacological interventions for heel lancing—the most common of the tissue-damaging procedures—whereas in 2011, of the 46% of infants who were exposed to tissue-damaging procedures, 14.5% were administered opioids and 14.3% received sweet-tasting solutions such as sucrose or glucose. Johnston et al. concluded that although the prevalence of painful procedures was lower in the more recent survey, pain management of procedures had generally not improved significantly.

In other countries, hospitalized infants were reported to experience an average of 12 tissue-damaging procedures per day (Carbajal et al., 2008). Carbajal and colleagues reported that, of 42 413 painful procedures performed on 430 infants, 79.2% of patients received no preprocedural analgesia, 2.1% received pharmacological interventions, while 18.2% painful procedures were managed using non-pharmacological strategies.

These data continue to support that there are a significant number of painful procedures performed on hospitalized infants and a gross undertreatment of procedural pain in infants.

### Children and adolescents

Several surveys have also been conducted to evaluate the prevalence of acute pain in hospitalized children and adolescents. In a recent audit of the epidemiology of procedural pain and pain management in 32 hospital units in eight paediatric hospitals in Canada, 2987 of 3822 children in the study had undergone at least one painful procedure in the preceding 24 hours with a mean of 6.3 painful procedures per child (Stevens et al., 2011). Of those who had a painful procedure, 78.1% had a pain management intervention recorded; however, only 28.3% had one or more pain management interventions administered and documented specifically for the painful procedure (Stevens et al., 2011).

Other researchers have focused specifically on acute pain intensity that is moderate to severe (e.g. >3 or 4 on a 10-point scale). Generally, prevalence rates from these studies are consistent and high; for example, Ellis et al. (2002) and Cummings et al. (1996) in cross-sectional studies reported a prevalence rate of 20–21% of clinically significant pain in hospitalized children in Canada. More recently, Groenewald et al. (2012) reported a prevalence rate of 27% of moderate to severe pain in hospitalized children in the USA. Adolescents and infants exhibited higher prevalence rates (38% and 32% respectively) than other children (17%). In addition, those hospitalized on surgical units demonstrated much higher rates of

moderate to severe pain (44%) than those on medical units (13%). Other studies described even higher prevalence rates of moderate to severe pain intensity; Taylor et al. (2008) stated that approximately 50% of hospitalized children from one tertiary level academic paediatric hospital reported moderate to severe pain during their stay with 23% reporting persistent pain.

Several studies indicate that child risk factors (e.g. age) and hospital service (e.g. surgical) are associated with the highest levels of moderate to severe pain (e.g. Groenewald et al., 2012; Stevens et al., 2011).

## Chronic pain

### Neonates and infants

As with acute pain, health professionals responsible for the care provision of infants and parents may harbour misconceptions or lack understanding of prolonged, persistent, or chronic pain in infancy. In a recent study by Pillai Riddell et al. (2009), two types of prolonged pain were described by the health professionals for hospitalized infants including '*chronically pained*' (a pain state that involved prolonged exposure of the infant to repetitive painful procedures, which was characterized by overlap with recovery from a previous painful procedure) and '*chronic pain*' (related to the aftermath of acute pain that is prolonged and has not resolved due to unknown cause) in infants. Examples of infants exhibiting chronic pain include: (1) a subgroup of postsurgical gastrointestinal patients ('short-gut babies') who continue to be distressed weeks after the completion of painful surgeries and reductions, (2) infants with chronic intestinal problems who suffer repetitive bouts of abdominal discomfort due to an inability to tolerate feeds and a distended abdomen, (3) infants who suffer from osteogenesis imperfecta, (4) infants who have sickle cell disease, (5) infants who have invasive malignant tumours, and (6) extremely low birth weight babies seen months/years later in follow-up clinics who would not weight bear or walk on their scarred heels (i.e. from repetitive heel lancing).

Anecdotal evidence from professional and parental caregivers suggests that there are significant numbers of medically comprised infants that are potentially experiencing chronic pain; however, there are no precise estimates of prevalence. These infants and young children may be even more vulnerable to the consequences of chronic pain and suffering as management strategies that are geared for the acute pain context may be ineffective. The longer untreated chronic pain continues in infancy, the more likely that maladaptive responses will develop later in life (Buskila et al., 2003; Hamilton and Zeltzer, 1994). Potential responses could include central nervous system sensitization, increased functional disability (Campo et al., 2001; Kashikar-Zuck et al., 2001), dysfunctional cognitive or emotional processes, (Eccleston and Crombez, 1999; Taddio, 1999; Taddio et al., 2002), and disrupted family functioning.

### Children and adolescents

Chronic pain has serious developmental and functional implications for children and adolescents (King et al., 2011). Chronic pain is common within chronic disease states (e.g. juvenile idiopathic arthritis (JIA), cancer) as well as outside disease states. As chronic pain may be associated both with children who are hospitalized, as well as those in the community, these two areas will be discussed together in this section, although chronic pain may also occur in children and adolescents cared for at home or in the community.

The first comprehensive review on the epidemiology of pain was published by Goodman and McGrath over two decades ago (Goodman and McGrath, 1991). Prevalence rates, time periods, measures utilized, and approaches to measurement are variable:

- ◆ Perquin et al. (2000), in school and population studies, evaluated 6000 Dutch children (aged 0–18 years) and found that 54% had experienced pain in the previous 3 months and a quarter had pain which lasted greater than 3 months with about 8% suffering from severe chronic pain. Chronic pain increased with age and was more common in girls.
- ◆ Abu-Saad (2010) noted that chronic pain is more likely in girls than boys and increases with advancing age.
- ◆ In a Greek study of over 8000 7-year-olds, recurrent complaints of pain (headache, abdominal pain, or limb pain which occurred at least once a week) occurred in 7.2% of the sample (8.8% of girls, 5.7% of boys;  $p < 0.001$ ) (Bakoula et al., 2006).
- ◆ In a Spanish point prevalence study of 561 8- to 16-year-olds, chronic pain (pain lasting more than 3 months experienced continuously or at least once or twice each month) was reported by 37% of the sample although in only 5.1% of the sample was the pain problem moderate or severe (Huguet and Miro, 2008).
- ◆ In a national survey of children in Canada that included 2488 10- to 11-year-olds, up to five times, every 2 years, across 12 to 19 years of age, weekly or more frequent incident rates ranged from 26.1% to 31.8% for headache, 13.5% to 22.2% for stomach ache, and 17.5% to 25.8% for backache (Stanford et al., 2008).
- ◆ Within the community population, in a Canadian study of approximately 500 13-year-olds, 96% experienced acute pain over the previous month. The most common acute pains were headache (78%), sore muscles (73%), and toothache (45%) (Van Dijk et al., 2006).
- ◆ Dangel (2005) reported that approximately 5% of school-age children experience recurrent abdominal pain (RAP), 5% to 10% experience chronic headaches, and 15% experience musculoskeletal pains with many receiving inadequate treatment.

King et al. (2011) used a comprehensive and rigorous approach to systematically review all of the existing literature, which included 41 studies. The prevalence of headache ranged from 8% to 83%; abdominal pain: 4% to 53%; back pain: 14% to 24%; musculoskeletal pain: 4% to 40%; multiple pains: 4% to 49%; and other pains: 5% to 88%. Prevalence of chronic pain was higher in girls and increased with age for most pain types. Lower socioeconomic status (SES) was associated with higher pain prevalence, especially for headache.

## Acute and recurrent pain in community health care settings

In addition to hospitalized children with a broad array of illnesses, children across the health-illness spectrum also experience a variety of acute and chronic pains. Although there is some overlap of acute, recurrent, and chronic pain, these entities will be loosely divided into pain of a more acute nature and those of a more chronic or persistent nature. Disease-related chronic pain will be discussed separately.

## Injection pain

Needle procedures, including injections, venous access procedures, heel sticks, and finger lances, are likely to be the most prevalent causes of iatrogenic pain. A child's interactions with medical providers are often coloured by the child's fear that s/he will get a shot or a poke. In the USA, healthy children undergo over three dozen separate vaccine injections by the time they reach adulthood (<<http://www.immunize.org/catg.d/p4050.pdf>>). A recent study demonstrated that approximately two-thirds of children have a fear of needles (Taddio et al., 2012). This problem persists into adulthood as approximately 25% of adults are afraid of needles (Taddio et al., 2012) and 10% meet the criteria for needle phobia (Hamilton 1995). For further discussion of pain associated with needle procedures see Taddio (Chapter 19, this volume).

## Dental/oral pain

Oral and dental pain is a frequent experience in children. Lifetime prevalence of oral pain in 5-year-olds is 25% (Moura-Leite et al., 2008) and in 8- to 10-year-olds is reported in 48% to 88% (Ratnayake and Ekanayake, 2005) with ranges for prevalence in the preceding 2 months of 24% to 70%. Up to 40% to 59% of children in prevalence studies report having had severe dental pain in the past. Pain impacted the child's ability to eat, sleep, play, and brush their teeth. Not surprisingly, dental caries are responsible for the majority of oral pain in children (Slade, 2001). Prevalence of oral pain is consistently higher in lower SES groups (Slade, 2001).

## Growing pains

The prevalence of growing pains varies widely between 2.6% and 49.4%. This disparity is likely to be because of the varying ages and definitions for this condition used in these studies. Recent studies using more rigorous methodology, larger sample size (532 and 596 children), and standard criteria which include only patients with pain that is intermittent, bilateral, not involving joints, occurring in the late afternoon or evening, with normal physical exam/and laboratory studies (Petersen et al., 2003) have found the incidence to be 24.5% and 36.9% respectively (Evans and Scutter, 2004; Kaspiris and Zafiropoulou, 2009).

## Musculoskeletal pain

Musculoskeletal pain is commonly reported by children of all ages. Studies vary as to the sites of pain evaluated (i.e. as a subset of all pain, all musculoskeletal pain, limb pain, or specific joint pain) as well as the reporting period (i.e. point prevalence, weekly, monthly, or more than monthly) and stratification by duration of involvement, which makes it difficult to compare findings. Musculoskeletal pain once a week occurs in 32%, and once a month in 38.9% of 9- to 11-year-old Finnish children (Mikkelsen et al., 1997) but once a week in 8.5% of Swedish 9- to 15-year-olds (Brun Sundblad et al., 2006), 40% of Brazilian children aged 10-to-18-years within the last 6 months (Zapata et al., 2006), and 45.1% of Italians aged 12 to 16 years had musculoskeletal pain with in the last 12 months (34.4% of who had pain which lasted longer than 3 months) (Masiero et al., 2010). Six per cent of 1000 consecutive visits to an urban paediatric clinic in the USA were for musculoskeletal pain (de Inocencio, 1998). The most common sites of pain include the knee, lower extremities, neck, and spine (de Inocencio, 1998; Masiero et al., 2010; Mikkelsen et al., 1997). Most studies found

that musculoskeletal pain prevalence increases with age and is more common in girls (King et al., 2011). Widespread musculoskeletal pain and lower limb pain both persist at a rate of about 30% of the initial population at 1- and 4-year follow-up (El-Metwally et al., 2005; Mikkelsen et al., 2008). For further discussion on inflammatory arthritis and arthropathies, see Chira and Schanberg (Chapter 22, this volume) and for non-inflammatory musculoskeletal pain, see Clinch (Chapter 24, this volume).

### Abdominal pain

Epidemiological studies of abdominal pain in youth vary by how abdominal pain, or more typically RAP, is defined. Some researchers use the definition by Apley and Naish (1958) of three episodes of abdominal pain over the previous 3 months that limit function; however, this is not universal. With the updating of the Rome criteria, differentiation of functional abdominal pain syndromes further into functional dyspepsia, irritable bowel syndrome, functional abdominal pain syndrome, and abdominal migraine further clouds this picture (Drossman, 2006).

In a USA study of 507 adolescents, 73% to 78% experienced abdominal pain in the past year, while it occurred weekly in 13% to 24% and impacted function in 17% to 24% of those surveyed (Hyams et al., 1996). Another US study of adolescent girls found a similar weekly prevalence with 20.7% reporting weekly stomach aches (Ghandour et al., 2004), while in a Canadian adolescent longitudinal sample the prevalence of weekly abdominal pain ranged from 13.5% to 22.2% (Stanford et al., 2008). In Iceland, over 2000 11- to 12- and 15- to 16-year-old children were surveyed. It was found that 18.4% of the sample had at least weekly abdominal pain, and there was a higher prevalence of pain in the younger group and in girls (Kristjánssdóttir, 1996). An Irish study evaluating epigastric pain symptoms in 1133 adolescents found 6% experienced epigastric pain at least once a week (Murray et al., 2007). In a Malaysian sample of 11- to 16-year-olds using Apley's criteria, the prevalence of pain was 10.2% (Boey et al., 2000).

Studies of younger children also use a variety of methodologies to evaluate the epidemiology of abdominal pain. In a Swedish study of 1155 6- to 13-year-olds, 39% experienced abdominal pain monthly, 19% experienced abdominal pain weekly, and an additional 8% had it more than once per week. Again girls experienced pain more often than boys (Petersen et al., 2003). In a population-based, retrospective birth cohort study conducted with 5700 children less than 5 years of age in Rochester, Minnesota, 11% of the sample sought care for abdominal pain at least three times within the first 5 years of life (Chitkara et al., 2007). Finally a British study that defined RAP as five or more episodes of pain over the previous year evaluated a cohort of almost 14 000 children. The prevalence of RAP increased from 3.8% at 2.5 years, to 6.9% at 3.5 years, to 11.8% at 6.5 years (Ramchandani et al., 2005). For further discussion on recurrent abdominal pain, see Schurman (Chapter 29, this volume).

### Headache

Headache is one of the most common pain complaints in children. Population studies of headache prevalence report that headache is frequently experienced by children and adolescents. Stanford et al.'s (2008) study of almost 2500 Canadian adolescents found that prevalence rates for weekly headache ranged from 26% to 31.8%, while 24.0% of American adolescent girls experienced headache weekly (Ghandour et al., 2004).

In younger children, Kroner-Herwig et al.'s (2007) study of German children aged 7 to 14, showed that headache prevalence in the last 6 months increased from 38.6% in 7- to 8-year-olds to 63.4% in 13- to 14-year-olds. The prevalence of weekly headache increased from 2.6% to 9.6%, while weekly prevalence was 23% in Swedish children (Petersen et al., 2003). Aromaa et al. (1998) found that 21.7% of 6-year-old Finnish children had a headache which impacted their daily activities within their lifetime.

Some studies differentiate the prevalence of migraine headache within larger headache samples using criteria defined by the International Headache Society by questionnaire or direct interview (Headache Classification Subcommittee of the International Headache Society, 2004). In Bille's prevalence study of 9000 Swedish children, 1.4% had migraine at 7 years of age increasing to 5.3% at 15 years of age (Bille, 1962). In a long-term follow-up of 73 of the children with migraine, 23% were migraine free by 25 years of age and 47% were migraine free by age 50 (Bille, 1997). Migraine prevalence was 9.9% in a cohort of Brazilian children aged 10-18 years (Barea et al., 1996), 10.4% in Turkish children aged 8-16 years (Bugdayci et al., 2005), and 10.6% in British children aged 5 to 15 years (Abu-Arefeh and Russell, 1994). For more on headache see Hershey (Chapter 31, this volume).

### Pain and obesity

Obesity is increasingly prevalent in children and adolescents though few studies have addressed pain in this population. Almost two-thirds of 270 overweight and obese children reported pain in a 1-month period (Lim et al., 2012). Obesity was a risk factor for musculoskeletal pain in a population-based cohort of over 3000 English children (Deere et al., 2012). Furthermore, being obese increased the odds of any pain (odds ratio (OR) 1.33), regional pain (OR = 2.04), and knee pain (OR = 1.87) (Deere et al., 2012). Obese patients' average pain was also more severe than their non-obese counterparts (Deere et al., 2012). Obesity was observed at a higher rate among youth presenting to a chronic pain clinic than a normative sample (20.8% versus 9.6%), and youth with back pain in this sample had a rate of obesity of 57% (Wilson et al., 2010).

### Contextual factors influencing chronic recurrent pain

As indicated in many of the previously discussed studies, there are several factors connected with the child and family that are associated with chronic and recurrent pain in children. These include: (1) age (e.g. where infants and adolescents often have higher prevalence and lower pain management strategies implemented), (2) sex (e.g. where girls often have higher pain prevalence and intensity than boys), and (3) diagnosis (e.g. JIA and number of joints evaluated). Factors such as SES also influence pain with greater prevalence of pain associated with lower SES in some situations (e.g. oral/dental pain).

Differences in definitions of pain (e.g. acute, chronic, persistent, prolonged, recurrent), in criteria for establishing pain diagnoses (e.g. International Headache Society criteria, Apley and Naish criteria), research methods (retrospective chart review, prospective survey or interview), data collection measures (whether validated or not), time or prevalence point, and reporting period also influence reported prevalence and paediatric pain distribution rates.

## Chronic disease-related pain

### Sickle cell disease

Pain is the most common symptom of sickle cell disease (SCD), and can begin early in the first year of life as levels of fetal haemoglobin decline in susceptible individuals, but remains poorly characterized. The frequency of pain episodes is consistently higher in the children who have hemoglobin SS or SB<sup>0</sup> thalassaemia compared with other genotypes. Most children with SCD have increasing pain episodes as well as pain-associated disability as they mature into adolescence and young adulthood. In a cohort of over 500 adults with SCD, 30% of respondents reported pain in greater than 95% of diary days. While 70% of emergency department visits in children with SCD are for pain, the large majority of these painful episodes continue to be managed at home (Dampier et al., 2002a, 2002b). Pain episode frequency is correlated with mortality (Platt et al., 1991). The average pain episode is 2 to 9 days in duration. For further discussion on sickle cell disease, see Dampier and Barakat (Chapter 25, this volume).

### Juvenile idiopathic arthritis/juvenile rheumatoid arthritis

The intensity of pain in JIA is quite variable; however, pain is frequent. Children with JIA report pain on 70% of days (Schanberg et al., 2003). Most children reported mild to moderate pain, but 25% of children reported pain in the severe range. Disease status typically predicts only a small to medium proportion of the variance in children's pain ratings (8–28%) (Malleeson et al. 2004; Schanberg et al. 1997; Thompson, 1987; Vandvik and Eckblad, 1990). Other variables such as demographic variables (possibly older age), psychological variables (such as coping and mood), and environmental factors (parent pain history) also determine pain report. For more on juvenile rheumatoid arthritis/JIA, see Chira and Schanberg (Chapter 22, this volume).

### Cancer pain

Pain is an almost universal symptom of childhood cancer, whether because of the disease itself, pain associated with treatment (mucositis, abdominal pain, surgery, neuropathic pain), or procedural pain from procedures such as venous access, lumbar puncture, and bone marrow aspiration. In interviews with children, Ljungman et al. (1999) found treatment-related pain to be the most severe pain problem associated with cancer (49%) with fewer reporting procedure-related pain (39%) and disease-related pain (13%) as the most severe pain problem. In a study of hospitalized children with cancer, more than half (27 of 49 patients) indicated they were experiencing pain. Eleven patients (22.4%) had mild pain, ten (20.4%) had moderate pain, and six (12.2%) had severe pain (Jacob et al., 2007). In a study of 164 youth dying from cancer, 92% experienced pain (Goldman et al., 2006). For cancer survivors, risk of reporting pain conditions and using prescription analgesics in adulthood were higher than sibling controls (Lu et al., 2011). For more on cancer pain, see Hickman et al. (Chapter 17, this volume).

## Infants and children with disabilities

In general, pain is common in children with disabilities due to the underlying disease state, under-recognition of pain, and association with medical care needs. Stevens and colleagues (Stevens et al.,

2003) reported that all neonates underwent more than ten painful procedures per day; those at the highest risk for neurological impairment had more procedures and received the least amount of analgesia during the first days of life.

In a pain diary study recorded of children with severe cognitive impairments over 2 weeks ( $n = 34$ ), 73% of the children had a painful experience on at least 1 day (Stallard et al., 2001). In a longitudinal study, children with moderate to profound intellectual disability ( $n = 94$ ) were found to experience pain for an average of 9 hour per week (Breau et al., 2003).

The majority of epidemiological studies in children with disability have been performed in children with cerebral palsy (CP). The prevalence of pain with CP is between 50% and 75% (Doralp and Bartlett, 2010; Parkinson et al., 2009; Tüzün et al., 2010). In a European study of 490 8- to 12-year-old children who could self-report and parents of 806 children (those who could and could not self-report), self-reported pain in the last week was 60% with parent-reported pain in the last 4 weeks of 73% (Parkinson et al., 2009). Self-reported pain was more frequent in older children but was not associated with disability severity, though parent-reported pain was associated with severity of disability. Other studies in CP have also found pain to be associated with severity of motor impairment (Houlihan et al., 2004). In 68 children with spina bifida, 56% experienced pain at least once a week, including headache in 88% with shunted hydrocephalus and 79% without hydrocephalus (Clancy et al., 2005).

The most common type of pain among children with CP is musculoskeletal pain. The most common sites of pain include feet, legs, back, hips, hands, and arms (Engel et al., 2005). Maximal pain is in the lower extremities in 70% of children (Ramstad et al., 2011). In addition, pain can result from commonly found secondary conditions including pressure ulcers and constipation.

## Implications for clinical practice, education, knowledge translation, and future research

Although considerable variability and inconsistency exist amongst definitions for various types of pain, measures and approaches to determining the prevalence of pain, and factors that influence pain, overall acute and chronic pain is common, and often under-recognized and undertreated in infants, children, and adolescents. This issue persists in clinical and community settings and includes hospitalized children who receive significant numbers of painful procedures during their hospital stay, healthy children in the community who are subjected to painful procedures associated with preventative/primary care (e.g. immunizations), and children with chronic illness who experience pain both while receiving care in the community and during repeated periods of hospitalization.

Decreasing the prevalence of pain requires increased efforts in prevention and implementation of better pain assessment and management strategies in all health care settings. Success in these areas requires behavioural change on behalf of both health care professional and parent care providers. Furthermore, awareness of the prevalence of paediatric pain and implementation of effective knowledge translation (KT) strategies is required and needs to be specifically targeted to particular audiences. Effective implementation of KT strategies requires a strong basis of evidence, a positive context where evidence is implemented (e.g. culture), and strategically planned methods of facilitating the translation of evidence into

useful products for users (e.g. clinical practice guidelines for health care professionals and tips or fact sheets for parents). Champions for change and a wide array of KT strategies including reminders, education, and audit and feedback for use in quality improvement initiatives are also required. An in-depth discussion of KT is provided by Yamada and Hutchinson (Chapter 61, this volume).

Research and evaluation form the basis for determining and reporting prevalence and distribution of paediatric pain and treatment. The research generally suffers from both methodological and interpretation problems. From a methodological perspective, samples are often inadequate and limited to single settings or clinical sites. Additionally, approaches to assessing prevalence and reporting period vary considerably and often non-validated/untested measures are used. Consistency in definition of types of pain, evaluation criteria, approach, measures, and timing of prevalence ratings would greatly enhance research in this area. Interpretation of results is often difficult due to methodological issues and inconsistent or wide-ranging prevalence estimates, which impact on potential changes in practice. Further efforts to critically evaluate

the quality of existing research (such as by King et al., 2011), standardize prevalence and pain definitions, and address areas which have received inadequate attention will assist in making interpretation of research results more meaningful and useful for both clinicians and researchers.

## Case example

Jackson is a 13-year-old boy who presents to his paediatrician with a 6-month history of episodic abdominal pain. The pain started the previous autumn. It comes on about 20 to 30 minutes after eating and is sometimes associated with diarrhoea. There is no blood in his stools; he has no fevers, or weight loss. His parents separated earlier this year. While his pain doesn't wake him from sleep he does have trouble falling asleep and will lie in bed for an hour or more several nights a week. Jackson has avoided going to friends' houses because he is afraid he will have pain or diarrhoea. He has missed over 2 weeks of school this year for abdominal complaints.

In a review of Jackson's pain history with his mother she describes several issues of pain in the past. As an infant Jackson had colic which resulted in several middle-of-the-night phone calls to his paediatrician. His parents learned to sooth him through these episodes by running the vacuum cleaner in his room.

When he was 3 years old, Jackson woke several times in the middle of the night with pain in his knees. He would cry out for his parents, they would give him ibuprofen, massage his back, or, on occasion, put him in a warm bath. By his fifth birthday these episodes had resolved.

Prior to starting school Jackson had developed a fear of receiving his immunizations—a problem which persists to the present day. For his yearly flu vaccination Jackson receives lidocaine prilocaine cream, and learned some guided imagery techniques from a family friend. His fear of needles extended to his interactions with his dentist and he required general anaesthesia to have three cavities filled.

At age 11 Jackson collided with a teammate while playing soccer. He landed on his back. He complained about pain in his lower back for several weeks before his parents sought medical treatment. He was diagnosed with a muscular strain and received physical therapy for 2 months before he could return to full activity without pain.

## CHAPTER 3

---

# Long-term effects of early pain and injury: animal models

Suellen M. Walker

### Summary

Nociceptive pathways are functional following birth and acute responses to noxious stimuli have been documented from early development in both clinical and laboratory studies. The ability of noxious afferent input to alter the level of sensitivity of nociceptive pathways in the adult nervous system, with, for example the development of central sensitization, is well established (Woolf, 2011). However, the developing nervous system has additional susceptibilities to alterations in neural activity, and increases due to pain and injury in early life may produce effects not seen following the same input at older ages. As a result, early tissue injury may lead to persistent changes in somatosensory processing and altered sensitivity to future noxious stimuli. The impact of early pain and injury cannot be simply viewed as increasing or decreasing sensitivity as results vary depending on the type and severity of injury and the outcomes used for assessment. Laboratory studies allow evaluation of different forms of injury, potential confounding factors, underlying mechanisms, and potential for modulation by analgesia.

### Introduction

Persistent alterations in pain sensitivity following early pain experience in neonates and infants are outlined by Grunau (Chapter 4, this volume). Clinical evaluations vary in their methodology, and it is clear that early pain experience does not simply either increase or decrease pain sensitivity. Preclinical studies similarly document differing long-term consequences of early pain and injury (Fitzgerald and Walker, 2009), and allow further evaluation of:

- ♦ The impact of different types and severity of early injury.
- ♦ Responses at different developmental stages to determine if there are critical periods during which alterations in normal development produce long-term effects.
- ♦ The mechanisms underlying persistent sensory changes.
- ♦ The degree to which the impact of early injury can be modulated by analgesia.

This chapter will firstly summarize factors that influence long-term effects in animal models with examples from different studies, and secondly, describe in more detail the specific effects of different forms of injury. In line with clinical reports, the majority of studies focus on injuries sustained within the neonatal period and early life. Laboratory studies allow evaluation of neural processes underlying the encoding and processing of noxious stimuli (i.e. 'nociception'), whereas the term 'pain' may be reserved for the human experience which encompasses cognitive and emotional dimensions; but for the purposes of this chapter 'pain' will also be used in association with behavioural and tissue responses to injury in animals.

### Evaluating the long-term impact of early pain: general principles

A number of different variables and outcomes can be assessed in preclinical studies evaluating the long-term impact of early pain, and as seen with clinical evidence, studies vary in their design and methodology.

### Extrapolation across species

Understanding the potential clinical significance of early life injury in animal models requires extrapolation to a similar developmental stage in humans. While direct translation of developmental age from rodents to humans, and the specific timing of events after birth, continues to be debated, the *sequence* of development of sensory and reflex systems in rodents correlate with those of human infants (Wood et al., 2003). Statistical models have been developed to translate development across species (Clancy et al., 2007b; Nagarajan et al., 2010), but are predominantly based on structural measures, and acknowledge that they cannot account for activity-dependent modification following birth (Clancy et al., 2007a). Maturation varies in different regions of the peripheral and central nervous systems, but in terms of spinal processing many approximate a postnatal day (P)3 rat with a preterm human neonate, P7 with an infant, P21 with an adolescent, and P35 with

young adulthood (Brambrink et al., 2010; Fitzgerald and Walker, 2009; McCutcheon and Marinelli, 2009; see also Walker and Baccei, Chapter 6, and Fitzgerald, Chapter 8, this volume for further details of the developmental changes in nociceptive signalling).

An additional difficulty relates to evaluating the potential 'effect size' of observations in animals models. For example, what degree of change in baseline sensory thresholds is likely to correlate with a clinically significant effect? Enhanced responses to future pain, which can result in alterations in the degree and duration of hyperalgesia, are more quantifiable and perhaps easier to translate to the clinical setting.

Ideally, effects in several species would be evaluated, and although primate studies are being performed to evaluate potential adverse effects of general anaesthesia in early development (Brambrink et al., 2010), resources for primate studies are limited. The majority of pain studies are performed in rats or mice, and the rodent has several advantages as a developmental model:

- ♦ Rodents are born at a relatively immature stage, thus allowing evaluation of effects that correlate with the preterm human infant. Mice and rats have similar gestation periods (19 and 21 days respectively) and then mature at similar rates.
- ♦ Rat pups are weaned at P21 and reach adulthood by 6 to 8 weeks of age, so persistent effects can be followed across a relatively compressed lifespan.
- ♦ Control animals in the same litter can be used to assess potential confounding effects due to handling and maternal separation.
- ♦ The ability of analgesics to modify persistent effects can be studied in a standardized comparative manner.

### Type of injury

A range of injuries can be utilized to model the many different sources of pain that may be experienced in early life, including: surgical injury, inflammation, repeated needle sticks, and visceral insults (see later sections for specific details). This allows evaluation of the response to specific components of various injuries, underlying mechanisms, and also allows comparison of the differential sensitivity to analgesic interventions.

### Impact on sensory function and/or response to future injury

Changes in baseline sensory sensitivity or in the response to a subsequent noxious stimulus in adulthood are the primary outcomes for assessing the long-term impact of prior pain and injury. Evaluation methods may include, but are not limited to, the following:

- ♦ Changes in behavioural sensory threshold, such as the threshold for hindlimb withdrawal from a mechanical stimulus applied to the hindpaw or the latency to withdraw from a thermal stimulus. A decrease in the mechanical threshold or thermal latency for withdrawal indicates increased sensitivity or *hyperalgesia*, and conversely an increase in threshold or latency indicates decreased sensitivity or *hypoalgesia*.
- ♦ *In vivo* electrophysiological recordings. Electromyography (EMG) can further quantify reflex sensitivity to threshold and suprathreshold stimuli. Extracellular recordings from cells in the dorsal horn assess responses to physical, chemical, or electrical stimuli or drugs; these may be applied to peripheral tissue

(e.g. hindpaw or gut), directly on the spinal cord, or by injection in other sites within the central nervous system (CNS).

- ♦ Detailed evaluation of activity in different ion channels at a cellular level. Patch clamp techniques on neurons within nociceptive pathways may be performed in slices of CNS tissue, including spinal cord, or *in vivo*.

Responses to stimuli of varying intensity can reveal differences in the distribution, time course, and underlying mechanisms of altered sensory processing. For example, neonatal inflammation produces late-onset generalized baseline hypoalgesia, as noted earlier in this section. In addition, an enhanced segmental hyperalgesia is unmasked by subsequent inflammation or incision in the previously injured, but not the contralateral paw (Chu et al., 2007; Ren et al., 2004).

The degree of hyperalgesia following injury in later life is frequently assessed. This may be in response to the same form of injury, such as repeat surgical incision (Beggs et al., 2012b) or re-inflammation of the hindpaw (Ren et al., 2004). Alternatively, different stimuli may be used to assess specific mechanisms (e.g. evaluation of C-fibre mediated responses by subsequent injection of capsaicin; Hohmann et al., 2005) or to evaluate the generalizability of altered sensitivity to different forms of injury (e.g. initial somatic injury and subsequent visceral sensitivity).

### Age at time of injury

The majority of current clinical and laboratory research focuses on long-term effects following pain experienced in the neonatal period and/or early infancy. An important feature of injury is early life is that effects in the developing nervous system may differ from those seen following the same injury at older ages. There are 'critical periods' when changing levels of neural activity can alter neural development (Hensch, 2004), but this period of vulnerability differs in different regions of the nervous system, and is also dependent on the type of injury.

To confirm specific developmental or age-dependent responses, the same injury must be performed and compared across a number of postnatal ages. In addition, the same *intensity* of stimulus should be delivered at each age. For example, the volume of inflammatory agent or irritant solution injected at different ages needs to be standardized for the rapidly changing size and weight of the animal, to confirm that enhanced effects following early injury are not due to a more severe injury or more intense acute stimulus in the youngest animals. The volume of the C-fibre stimulant mustard oil applied to the hindpaw has been adjusted according to the size or 'volume' of the paw at different ages (Jiang and Gebhart, 1998), the volume of capsaicin altered to produce comparative local responses (S. M. Walker et al., 2007), and anatomical landmarks used to produce incision of the same relative proportion of hindpaw at different ages (S. M. Walker et al., 2009).

### Time interval before evaluation

The impact of neonatal injuries on different outcomes may change with time. Ideally the time course of response should be evaluated by regular assessments until the animal or the system being evaluated is fully mature, as rodents may be considered 'adult' at different ages (McCutcheon and Marinelli, 2009). Peripheral nociceptive mechanisms mature relatively early, but spinal cord

processing, and particularly modulation by descending pathways from the brainstem (Hathway et al., 2009, 2012) is not mature until the 3rd to 4th postnatal week (see Fitzgerald, Chapter 8, this volume). Following neonatal inflammation, a clear change is seen as the animal matures, with generalized hypoalgesia or decreased baseline sensitivity emerging only after P30 (Ren et al., 2004), potentially due to alterations in descending modulation (Zhang et al., 2010).

### Non-sensory behavioural outcomes

The effect of early injury on anxiety in adulthood has been assessed using established paradigms, but results vary with the type and intensity of initial stimulus. A low anxiety trait in adulthood (P50–55) followed early inflammation (0.25% carrageenan at P3) as assessed by: more time spent in the open arms of an elevated plus maze; enhanced ability to cope with stress related to a forced swim test; and reduced basal and stress-related neuroendocrine markers at rest and following the swim test (Anseloni et al., 2005). Conversely, more severe hindpaw inflammation (10 mcl of complete Freund's adjuvant (CFA) in P1 mice) *increased* anxiety behaviours in adulthood (fewer entries into open arms of elevated plus maze at P90; Roizenblatt et al., 2010). Formalin in P1 rats (10 mcl 4% into right forepaw and hindpaw) reduced exploratory behaviour in males and increased anxiety (reduced time in open arm of elevated plus maze) in females (Negri et al., 2011). Similarly, daily formalin injections (5 mcl of 4%) into each hindpaw from P1 to P4 reduced exploratory behaviour and impaired learning in a radial arm maze test (Anand et al., 2007; Rovnaghi et al., 2008). Repeated hindpaw needle pricking from P0 to P7 was also postulated to increase vulnerability to stress and anxiety-mediated behaviours, as deficits in exploratory and defensive withdrawal behaviour were found at P65, but without differences in stress hormones (Anand et al., 1999).

An early visceral insult (repeated colorectal distension from P8 to P21) also reduced exploratory activity in adulthood (J. Wang et al., 2008). Interestingly, most models associated with increased anxiety also produced long-term *increased* pain sensitivity (reduced hind-limb withdrawal sensory thresholds); whereas carrageenan inflammation produces generalized *hypoalgesia* and reduced anxiety. This potential link between the pattern of pain and anxiety outcomes requires further evaluation.

As central pathways involved in pain and reward processing are linked, the long-term impact of repeated neonatal hindpaw incision (at P3, P10, and P17) on motivational behaviour in adulthood was tested. Exploratory behaviours in adulthood were not altered by neonatal incisions or anaesthesia. Following a subsequent incision in adulthood, motivational behaviours were similar, but activity in orexin neurons in the lateral hypothalamus (an important region for reward signalling) was increased (Low and Fitzgerald, 2012).

For some behaviours the link with pain signalling is less clear. For example, ethanol preference was reduced after repeat formalin injection (Bhutta et al., 2001), but was increased following repeat needle stick injury (Anand et al., 1999).

### Tissue analysis and mechanisms

An obvious advantage of laboratory studies is the ability to analyse tissue at various sites to evaluate both the impact of the initial injury and any long-term consequences in structure and/or function. Examples include:

- ♦ Assessing the localized response to injury in the peripheral tissue (e.g. degree of persistent inflammation or changes in innervation).
- ♦ Evaluating changes in receptor expression in the cell bodies of peripheral afferents in the dorsal root ganglion (DRG) or spinal cord or other CNS regions using antibodies to the receptor (immunohistochemistry) or measuring receptor protein levels (Western blot).
- ♦ Alterations in gene expression which indicate neuronal activation (e.g. c-fos) or which relate to specific mechanisms mediating long-term consequences (e.g. upregulation or downregulation of genes controlling receptors, transmitters, or signalling pathways involved in nociceptive function). Use of genetically modified mice can also provide further insights by comparison of wild-type strains with animals in which a portion of the gene is permanently non-functional (knockout), inactivated in a tissue- or time-specific manner (conditional knockout), or briefly silenced (knockdown).

### Pharmacological interventions

Pharmacological strategies may be used to further define mechanisms associated with the effects of early pain and injury. For example, in addition to immunohistochemistry studies showing altered microglial morphology and increased reactivity, a reduction in hyperalgesia by administration of an inhibitor of microglia (e.g. minocycline) further established the role of microglia in mediating effects of prior neonatal incision (Beggs et al., 2012b). Similarly, prevention of long-term consequences by local anaesthetic blockade of peripheral nerves supplying the area of injury (S. M. Walker et al., 2009), not only confirms that activity within primary afferent fibres has a mechanistic role, but also suggests a potential therapeutic intervention. Administration of drugs by different routes can more closely evaluate the site of action: comparing responses following intrathecal administration rather than systemic (oral, subcutaneous, intraperitoneal, intravenous) administration identifies selective spinal cord effects; and localized small volume injections into the brain can evaluate the impact of altering function in different brain regions.

Assessing modulation of long-term effects by analgesics has important clinical implications. Two different aspects may be evaluated: (1) the ability of different forms of analgesia at the time of the initial insult to modify or prevent long-term consequences; and/or (2) the ability of different analgesics to effectively manage any alterations in pain response at the time of injury in later life.

### Sex differences

The degree to which male or female sex influences the susceptibility to long-term consequences of early injury varies, both with the type of initial injury and with the outcome being assessed. Although not all studies include comparison of female and male animals, alterations in either the degree or type of long-term impact of neonatal interventions have been reported in some, but not all, studies and warrant further evaluation (Cataldo et al., 2010; LaPrairie and Murphy, 2007, 2010; Negri et al., 2011). At this stage, it is not possible to reliably conclude whether males or females are more susceptible.

## Maternal separation, handling, and neonatal stress

As developmental studies involve experiments on young animals that are dependent on maternal care, it is necessary to control for non-injury related effects due to handling and separation or interactions with the mother (Sternberg and Ridgway, 2003).

Repeated and often prolonged maternal separation, for up to 3 hours a day across the first 2 postnatal weeks, increases visceral sensitivity in adulthood (Chung et al., 2007; Schwetz et al., 2005; Tjong et al., 2010). Alterations in subsequent stress-induced analgesia (Sternberg and Ridgway, 2003) and opioid tolerance (Kalinichev et al., 2002) suggest changes in endogenous pain inhibitory systems. This degree of handling and duration of separation is predominantly utilized to assess changes in stress-related behaviour mediated via the hypothalamic–pituitary–adrenal axis (Chung et al., 2007; Faturi et al., 2010), and is greater than required for most neonatal injury models. However, control groups with the same degree of handling and separation in the absence of the noxious stimulus are required to confirm that effects seen in later life are specific for the injury itself.

The impact of maternal–pup interactions is complex, as injury in the pups may also alter maternal behaviour and outcomes. An initial increase in maternal contact but later neglect was reported after hindpaw inflammation in rat pups (Anseloni et al., 2005), but no change in maternal behaviour was seen following laparotomy in newborn mice (Sternberg and Ridgway, 2003; Sternberg et al., 2005). Maternal care may modulate adverse effects: increased grooming was noted after P6 and was postulated to decrease the impact of repeated heel prick from P2 to P14 in rats (C. D. Walker et al., 2003). In a subsequent study, varying levels of grooming by different mothers influenced thermal withdrawal latency in adulthood, but had no impact on long-term effects following repeated formalin injection (twice daily from P3 to P14; C. D. Walker et al., 2008). The need to care for injured pups may also alter maternal outcomes, with one study reporting long-term alterations in pain threshold, anxiety, and sleep fragmentation in the dams of pups with CFA-induced hindpaw inflammation (Roizenblatt et al., 2010).

## Evaluating the long-term impact of early pain: specific injury models

A large number of different injury models have evaluated the impact of early pain, and responses vary both with the type and severity of initial injury (Fitzgerald and Walker, 2009) (Figure 3.1).

### Peripheral inflammation

#### Initial injury

Different agents can induce a peripheral inflammatory response, are commonly injected in the hindpaw, and changes in hindlimb reflex sensitivity assess the degree of subsequent sensitivity. CFA comprises inactivated mycobacteria emulsified in mineral oil, and carrageenan contains polysaccharides extracted from seaweeds.

Long-term effects following neonatal inflammation vary with the type and severity of stimulus. An early model documenting persistent changes in sensory processing utilized 25 mcl CFA on P1 (Ruda et al., 2000), however this is a relatively large volume in the neonatal paw, producing chronic inflammation rather than a specific neonatal insult (Lim et al., 2009; S. M. Walker et al., 2003). Hindpaw

injection of carrageenan in different volumes and concentrations (0.5–2 mcl/g of 0.25–2%) produces a robust but shorter duration acute inflammatory hyperalgesia (Ren et al., 2004; Torsney and Fitzgerald, 2002; S. M. Walker et al., 2003), and doses as low as 1 mcg/g of 0.25% lambda carrageenan produce persistent effects (Anseloni et al., 2005; Ren et al., 2004; G. Wang et al., 2004).

#### Impact on sensory thresholds

Large volumes of CFA in neonatal rodents (25 mcl in P1 rat or 20 mcl in P1 mouse) have been associated with either no change (Lim et al., 2009; Ruda et al., 2000; S. M. Walker et al., 2003) or a reduction in sensory thresholds (i.e. increased sensitivity) (Blom et al., 2006; Roizenblatt et al., 2010) in adulthood. By contrast, carrageenan (1 mcl/g 0.25%) has been consistently associated with higher thresholds (i.e. decreased sensitivity) from P30 until adulthood (Anseloni et al., 2005; Lidow et al., 2001; Ren et al., 2004; G. Wang et al., 2004). In addition to a generalized hypoalgesia in all paws, neonatal carrageenan also decreased the visceromotor response to colorectal distension in adulthood, suggesting a modulatory impact on both somatic and visceral processing (G. Wang et al., 2004).

#### Response to subsequent noxious stimulus

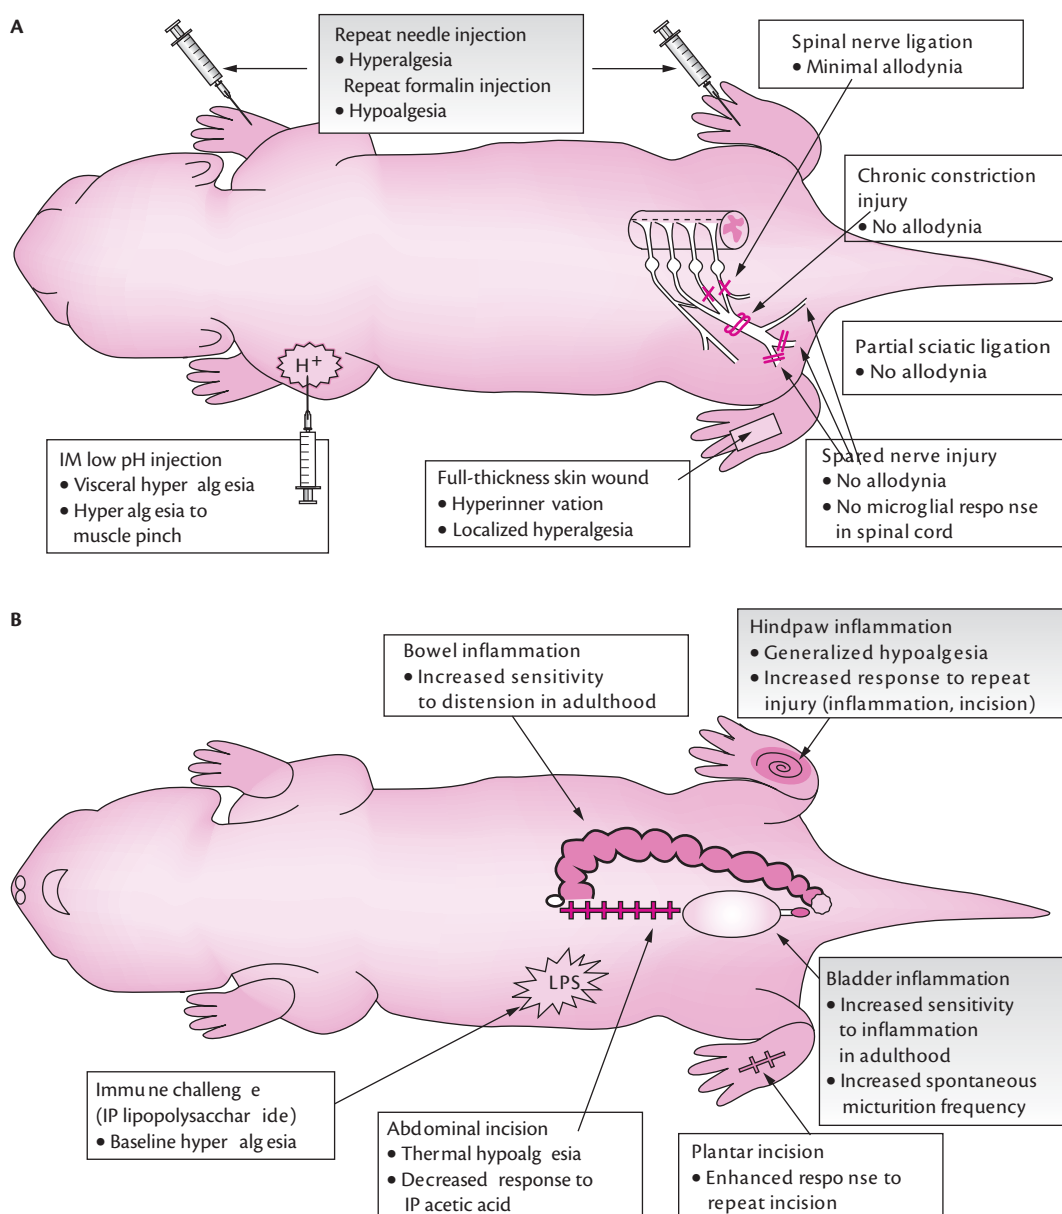

Neonatal hindpaw inflammation increases the response to noxious stimuli in adulthood. CFA 25 mcl at P1 enhanced the response to different stimuli in the previously injured paw including: increased behavioural hyperalgesia following repeat CFA (Lim et al., 2009; Ruda et al., 2000) or capsaicin (Hohmann et al., 2005); earlier onset of response to formalin; and increased dorsal horn neuronal response to peripheral brush or pinch (Ruda et al., 2000). Prior CFA inflammation did not alter the response to nerve injury in adulthood (Lim et al., 2009). Neonatal carrageenan inflammation also increases the degree of behavioural hyperalgesia to subsequent inflammation (Ren et al., 2004) or incision (Chu et al., 2007) of the previously injured paw.

#### Critical period

The first postnatal week is the critical period for persistent effects following inflammation. Persistent changes follow CFA 25 mcl at P1, but not 50 mcl CFA at P14 in rats (Hohmann et al., 2005; Ruda et al., 2000) and CFA 20 mcl at P1 but not 40 mcl at P14 in mice (Blom et al., 2006). However, it is difficult to determine if these volumes produced the same degree of inflammation at the two ages. Carrageenan in doses adjusted for body weight (1 mcl/g) at P0, P1, P3, and P5 but not at P8 and older was associated with long-term alterations in threshold (Ren et al., 2004), and the pattern of gene expression in the dorsal horn also differed if injury occurred at P3 rather than at P12 (Ren et al., 2005). Similarly, altered behaviours indicative of a low anxiety trait in adulthood were seen following carrageenan inflammation at P3 but not P12 (Anseloni et al., 2005).

#### Mechanisms

Injection of CFA 25 mcl in newborn rat pups produces long-term increases in paw diameter (not seen after carrageenan or smaller volumes or CFA) and histological signs of chronic inflammation (Lim et al., 2009; S. M. Walker et al., 2003). This may contribute to the persistent reductions in sensory threshold that have been reported following this stimulus (Blom et al., 2006; Roizenblatt et al., 2010).

**Figure 3.1** Diagrammatic representation of different early injuries and associated impact on long-term sensory outcomes. See text for further details. IM, intramuscular; IP, intraperitoneal.

As the baseline *hypoalgesia* following carrageenan is generalized to all paws and emerges later in development (after P30), brain-stem-mediated alterations in descending modulation have been postulated (G. Wang et al., 2004). Enhanced inhibition from the rostroventral medulla (RVM; Zhang et al., 2010) and alterations in opioid-mediated response in the periaqueductal grey (PAG; Laprairie and Murphy, 2009) have been noted in adults following neonatal hindpaw carrageenan. Increased expression of several subtypes of serotonin (5HT) receptor in the PAG has also followed early inflammation (Anseloni et al., 2005).

Different mechanisms are likely to underlie the enhanced hyperalgesic response to noxious stimuli in adulthood, which differs in both time course and distribution from changes in baseline threshold.

Enhanced re-injury responses are apparent from soon after the initial injury and are segmentally restricted to the previously inflamed paw (Chu et al., 2007; Ren et al., 2004). Following CFA 25 mcl at P1 (Ruda et al., 2000) (but not CFA 5 mcl or 25 mcl carrageenan; S. M. Walker et al., 2003), the terminal field of sciatic nerve afferents was expanded in the ipsilateral spinal cord, with increased calcitonin gene-related peptide-positive terminals. This likely contributes to an enhanced central response to a noxious peripheral stimulus, as supported by increased *c-fos* expression in response to repeat CFA (Tachibana et al., 2001) or capsaicin in adulthood (Hohmann et al., 2005). Long-term alterations in the spinal cord expression of genes related to nociceptive transmitter systems (Ren et al., 2005), and in the function and/or structure of N-methyl-D-aspartate receptors in the spinal cord

(Chu et al., 2007) and in the thalamus and other brain regions (Blom et al., 2006) may also contribute to enhanced responses to subsequent injury.

### Modulation by analgesia

The long-term impact of neonatal carrageenan inflammation was reduced by morphine at the time of the initial insult (Laprairie et al., 2008; Rahman et al., 1997).

## Formalin injection

### Initial injury

Injection of formalin (0.5–15%) into the hindpaw is used as a model of acute nociception and produces a biphasic behavioural response with licking, twitching, flicking, and elevation of the paw in adult rats (Le Bars et al., 2001). Although responses differ in neonatal rat pups, formalin does produce specific nociceptive behaviours that are reduced by morphine (Abbott and Guy, 1995; Barr et al., 2003; McLaughlin et al., 1990).

### Impact on sensory thresholds

Repeated injection of 5 mcl of 10% formalin (all four paws at P1 and forepaws or hindpaws on alternate days from P2 to P7; Bhutta et al., 2001) or daily injections into each hindpaw from P1 to P4 (5 mcl of 4%; Anand et al., 2007; Rovnaghi et al., 2008) decreased thermal sensitivity in adulthood. As responses were compared to undisturbed controls, the impact of repeated injection versus the formalin injectate itself cannot be determined. By contrast, formalin at a single time point (10 mcl of 4% into right forepaw and hindpaw on P1) had no impact on thermal latency in adulthood (Negrigo et al., 2011). Twice-daily injections of a lower concentration of formalin (10 mcl 0.2–0.4%) in alternating hindpaws from P3 to P14 also had no impact on thermal sensitivity in adulthood (C. D. Walker et al., 2008).

### Response to subsequent noxious stimulus

Repeated formalin from P3 to P14 increased the area under the behavioural response curve following subsequent hindpaw formalin in adulthood (C. D. Walker et al., 2008).

### Critical period and mechanisms

There has been limited comparison of age-dependent susceptibility for persistent effects following formalin, as many protocols include repeated injections across the first 1 to 3 postnatal weeks. Histological evaluation of the effect of repeated formalin injection on the peripheral tissue would be beneficial to exclude chronic injury. The pattern of gene expression in the spinal cord differed following hindpaw formalin injection at P3 (5 mcl or 20 mcl of 2%) versus P21 (200 mcl of 2%; Barr et al., 2005).

### Response to analgesia

Long-term behavioural changes in adults were reduced by morphine administration prior to neonatal formalin injection (Bhutta et al., 2001). Ketamine reduced the thermal hypoalgesia in adult females, but not in males (Anand et al., 2007).

## Repeat needle injury

### Initial injury

Repeated needle injection in the paws of rat pups has been performed to model repeated heel lance for clinical blood sampling in neonates. However, the relative size of the needle and depth of penetration may be relatively greater in the rodent paw.

## Impact on sensory responses

A 25-gauge needle was inserted through each paw, once, twice, or four times daily from P0 to P7. Thermal sensitivity was increased in the four-times daily injection group at P16 and P22. This may reflect residual inflammation, as there was no significant difference from controls by P65 (Anand et al., 1999).

Repeated unilateral injections in the gastrocnemius muscle on alternate days from P8 to P20 were performed with a needle alone or combined with injection of 100 mcl of an acidic pH 4 or physiological pH 7.4 saline solution. No intervention altered reflex sensitivity to a hindpaw mechanical stimulus in adulthood (Miranda et al., 2006).

### Response to subsequent noxious stimulus

Although there were no detectable changes in muscle histology, the response to deep muscle pinch was enhanced following repeated muscle injection of the pH 4, but not pH 7, solution. Additionally, the pH 4 group had an increased visceromotor response (EMG response in abdominal muscles) and spinal dorsal horn neuron response (in areas of viscerosomatic convergence) to colonic distension in adulthood, which may reflect more generalized alterations in descending modulation (Miranda et al., 2006).

## Full-thickness skin wound

### Initial injury

Neonatal skin is thin and sensitive to injury (Fox, 2011). In the laboratory, long-term effects have been evaluated following removal of a small full-thickness skin flap on the dorsal hindpaw (Reynolds and Fitzgerald, 1995).

### Impact on sensory responses

Neonatal skin wounding produces localized hyperalgesia that persists well beyond the period of wound healing (Alvares et al., 2000; Reynolds and Fitzgerald, 1995; Young et al., 2008).

### Critical period

Persistent hyperalgesia follows full-thickness skin wounding in the first postnatal week, but not at older ages, and the degree of hyperinnervation is much greater than seen following the same injury in adulthood (Reynolds and Fitzgerald, 1995).

### Mechanism

Full-thickness skin wounds result in both peripheral changes in innervation density and central changes in the spinal cord. Marked peripheral hyperinnervation due to collateral sprouting from adjacent axons, and from distant intact neurons (Alvares and Fitzgerald, 1999), occurs within the wounded area, mediated by local release of neurotrophic factors including NGF and NT-3 (Beggs et al., 2012a; Constantinou et al., 1994; Reynolds et al., 1997). In addition, there are changes in short-range neural inhibitory cues (Moss et al., 2005). Ephrins act as contact-mediated guidance molecules during development and repair, and ephrin-A4 inhibits neurite outgrowth. However, following neonatal skin wounding this inhibition is reduced as ephrin-A4 expression is downregulated, allowing an increase in innervation density (Moss et al., 2005). NK-1 expressing neurons in the spinal cord are involved as ablating these neurons with intrathecal substance P-saporin at the time of neonatal injury or in adulthood reduced injury-related effects (Young et al., 2008). In addition, the receptive field size of dorsal horn neurons is significantly greater 3 and 6 weeks following neonatal skin wounding when compared with control animals (Torsney and Fitzgerald, 2003).

### Modulation by analgesia

A single sciatic block with bupivacaine prior to skin wounding produced an acute sensory and motor block but did not prevent hyperinnervation or persistent hyperalgesia (De Lima et al., 1999). Intra-articular injection of lidocaine in the medial and lateral ankle reduced acute vocalizations following stimulation of the injured hindpaw, although it is not clear how frequently injections were performed, and there was no impact on persistent effects (Young et al., 2007).

### Surgical incision

#### Initial injury

Surgical injury produces inflammation, skin wounding, and peripheral nerve injury (Kehlet et al., 2006). The plantar hindpaw incision model comprises skin incision plus elevation and incision of the underlying plantaris muscle, and produces acute hyperalgesia and increased hindlimb reflex sensitivity at all postnatal ages in the rat (Ririe et al., 2003; S. M. Walker et al., 2009). A midline abdominal incision in mice on the day of birth has also evaluated the impact of neonatal laparotomy (Sternberg et al., 2005).

#### Impact on sensory responses and future injury

Neonatal laparotomy in mice was associated with a generalized decrease in baseline sensitivity to thermal and visceral stimuli in adulthood (Sternberg et al., 2005). Similarly, and as seen following carrageenan inflammation, neonatal hindpaw incision decreases baseline sensitivity to mechanical and thermal stimuli in adulthood, but a subsequent injury unmasks segmental hyperalgesia. Both the degree and duration of hyperalgesia are increased when the same paw is re-injured, either 2 weeks later or in adulthood (P60) (Beggs et al., 2012b; S. M. Walker et al., 2009). A series of three hindpaw incisions performed at P3, P10, and P17 also increased the degree of incision-related hyperalgesia at P90 (Low and Fitzgerald, 2012).

#### Critical period

Hindpaw incision in the first postnatal week (P3 or P6) but not at older (P10, P21, P40) ages enhanced the response to future incision (S. M. Walker et al., 2009).

#### Mechanism

Prior neonatal incision primes the spinal neuroimmune response to repeat incision in adulthood. The enhanced incision-related hyperalgesia in adults with prior neonatal incision is associated with an earlier onset, and increased duration and degree of microglial reactivity in the spinal cord (Beggs et al., 2012b).

### Modulation by analgesia

Administration of systemic morphine at the time of neonatal laparotomy prevented long-term changes in sensory responses (Sternberg et al., 2005). The effect of neonatal incision on later incision-related hyperalgesia was prevented by repeated perioperative sciatic blocks (four 2-hourly blocks) but not by a single preoperative block, suggesting that more prolonged primary afferent blockade is required to modify persistent effects. In adults with prior neonatal incision, intrathecal minocycline selectively prevents the enhanced hyperalgesic response, confirming a functional role for microglial reactivity (Beggs et al., 2012b; see Vega-Avelaira and Beggs, Chapter 7, this volume, for further details of neuroimmune interactions in nociceptive pathways).

### Visceral injury

#### Initial injury

Visceral injury is modelled in rodents by exposing the bladder or to bowel to chemical irritants, such as mustard oil or zymosan, or repeated mechanical stimuli (e.g. rectal distension).

#### Impact on sensory responses and future injury

Early visceral injury has been associated with visceral hyperalgesia in adulthood. Daily mechanical distension or chemical (mustard oil 0.2 ml 5%) colonic irritation from P8 to P21 increased behavioural (Al-Chaer et al., 2000) and abdominal muscle EMG responses to subsequent colonic distension, and also altered food consumption and faecal output (J. Wang et al., 2008). Shorter exposures to intracolonic mustard oil (2% 10 mcl from P8 to P10; Christianson et al., 2010) or infusion of acetic acid at P10 (Winston et al., 2007) also increased sensitivity to mechanical colonic distension in adulthood.

Bladder inflammation (daily intravesical injections of zymosan P14–P16) increased spontaneous micturition frequency and the response to subsequent inflammation in adulthood (Randich et al., 2006).

Spinal neurons receive convergent input from both somatic and visceral afferents, and neonatal visceral injury increased somatic reflex sensitivity to hindpaw thermal (J. Wang et al., 2008) or mechanical stimuli (Christianson et al., 2010), in some but not all models (Randich et al., 2006). Neonatal somatic insults also have an impact on visceral sensitivity in adulthood, as noted in previous sections (Miranda et al., 2006; G. Wang et al., 2004).

#### Critical period

Visceral insults in the first 2 to 3 postnatal weeks, but not at older ages, have been associated with persistent changes in sensitivity, including: repeat colonic stimulus from P1 to P20 but not P21 to P42 (Al-Chaer et al., 2000); daily bladder injections from P14 to P16 but not P28 to P30 (Randich et al., 2006); intracolonic acetic acid at P10 but not 8 weeks of age (Winston et al., 2007).

#### Mechanism

Neonatal colonic irritation increased electrophysiological responses in adult spinal cord viscerosensitive neurons, in the absence of any demonstrable changes in peripheral bowel histology (Al-Chaer et al., 2000; Christianson et al., 2010; Lin and Al-Chaer, 2003). Changes in receptor expression in the DRG may reflect the nature of the initial insult. Increased TRPV1 expression in cell bodies of colon afferents in the DRG followed acetic acid irritation at P10 (Winston et al., 2007); whereas P8 to P10 mustard oil (which stimulates TRPA-1 receptors), increased expression of TRPA-1 but not TRPV1 (Christianson et al., 2010).

### Immune challenge

#### Initial injury

Early life immune challenges are modelled by various stimuli, such as injection of the bacterial endotoxin lipopolysaccharide (LPS) or endothelin-1, and can have a significant impact on the immune response in later life (McKelvy and Sweitzer, 2009; Spencer et al., 2011).

#### Impact on sensory responses and mechanisms

Intraperitoneal LPS at P14 had persistent effects on sensory function, as hindpaw sensitivity to mechanical and thermal stimuli and spinal

expression of cyclo-oxygenase 2 was increased in adulthood (Boisse et al., 2005). Similarly, intracerebral injection of LPS at P5 produced persistent hyperalgesia and increased microglial reactivity in the brain, which was attenuated by administration of an interleukin-1 receptor antagonist (K. C. Wang et al., 2011). As severe inflammation may be associated with a significant immune response, and increased microglial reactivity in the spinal cord has been associated with persistent alterations in pain sensitivity, interactions between the immune system and nociceptive processing can have a significant impact on the long-term consequences of early injury.

## Peripheral nerve injury

Several different models have been used to investigate the pathophysiology of traumatic nerve injury and ontogeny of neuropathic pain (Sorkin and Yaksh, 2009). In rodents, injury to the sciatic nerve or its branches or related central spinal nerves allows evaluation of changes in hindlimb reflex responses to hindpaw sensory stimuli, and comparison both with baseline and the contralateral side. Spared nerve injury, chronic constriction injury, partial sciatic ligation, and spinal nerve ligation performed in the first 2 to 3 weeks of postnatal life do not produce the same degree of acute allodynia as seen in adults (Howard et al., 2005; Lee and Chung, 1996; Ririe and Eisenach, 2006). Less commonly, nerves innervating the tail are injured and tail flick responses are used to evaluate sensitivity (Back et al., 2008). Age-related differences in the glial response to nerve injury contribute to the lack of neuropathic allodynia in early life. The effects and mechanisms of nerve injury are discussed by Vega-Avelaira and Beggs (Chapter 7, this volume).

## Conclusion

Both clinical and preclinical studies demonstrate the complexity and diversity of persistent changes in pain responses following early pain and injury. It is too simplistic to expect that pain experience will reliably either increase or decrease sensitivity, as multiple contributory factors may interact to influence nociceptive processing and/or the behavioural response to pain. Evaluation in animal models is essential to investigate age-dependent changes in both the acute and persistent effects of different forms of injury, understand underlying mechanisms, and ultimately how effects may be modified or prevented by clinically applicable analgesic interventions.

## CHAPTER 4

---

# Long-term effects of pain in children

Ruth E. Grunau

### Introduction

Major advances in high-technology medical care have led to greatly increased survival of medically fragile infants born extremely pre-term, or with major congenital anomalies or other life-threatening conditions. These infants are exposed to procedural, surgical, and post-surgical pain. For millennia human infancy was a prolonged period of adult protection, with pain rarely encountered early in life. While the biological mechanisms for perception of pain develop during the fetal period, endogenous capacities to dampen pain mature later. Until relatively recently, this biological substrate was a good fit, matching the environment of infancy. However, the revolution in medical care has led to unforeseen challenges to understand and manage infant pain. In full-term infants, the primary concern is whether early pain alters later pain sensitivity. In contrast, due to the immaturity of the developing nervous system, the greatest impact of pain is likely to occur in the least maturely born infants. Therefore, in infants born very preterm who undergo lengthy hospitalization, pain may affect multiple aspects of development. This chapter focuses on long-term effects of early pain on subsequent pain perception, neurodevelopment, brain development, and programming of stress systems in the context of clinical studies, and whether caregiving factors may ameliorate potential long-term adverse effects.

### Full-term infants: early pain and later pain thresholds

Stimulation of peripheral nociceptors can trigger long-term changes in circuitry of the central nervous system (CNS; Fitzgerald and Walker, 2009). To better understand the potential long-lasting changes associated with early pain in infants born full-term, studies of the effects of circumcision, major surgery and burns on tactile and pain thresholds later in childhood have been conducted.

### Circumcision

One line of investigation to evaluate whether neonatal pain has long-term effects in healthy infants born full-term, has been follow-up of subsequent pain sensitivity in boys circumcised early in life. In a post hoc analysis of behavioural response to immunization

pain, boys who had been circumcised (regardless of analgesia) displayed greater pain behaviour to immunization at age 4 to 6 months, compared to uncircumcised boys (Taddio et al., 1995). Then a prospective randomized controlled study was conducted in which boys underwent neonatal circumcision with either local anaesthetic lidocaine-prilocaine 5% cream (EMLA®) or placebo, or were not circumcised. These three groups of boys were studied later during immunization at age 4 to 6 months (Taddio et al., 1997). Circumcised boys who had received placebo showed higher facial actions, cry duration, and observer visual analogue scale (VAS) pain ratings in response to immunization compared to the uncircumcised group.

Importantly, using quantitative sensory testing, adult penile sensitivity did not differ in men who had or had not been circumcised as neonates (Bleustein et al., 2005). Long-term effects of circumcision on pain threshold may be transitory. There is scant research on this question, given that placebo studies for neonatal circumcision studies are no longer ethical by current standards. Further studies are needed that compare later pain thresholds among infants that receive varying pain relief for circumcision (e.g. lidocaine-prilocaine 5% cream versus penile block). Moreover, caregiver behaviours during immunization should be measured to rule out possible confounding factors between parents who choose to circumcise their newborn boys, compare to those who do not.

### Major surgery

Long after surgery early in life, there appear to be changes in later tactile sensitivity that vary depending on the type of surgery, and whether in the region of surgery or elsewhere, indicating both local and global effects. In a combined sample of children born full-term or preterm, skin sensitivity was tested at age 9 to 12 years in a group of children who had chest surgery in infancy, and compared with children who had no surgery (Schmelzle-Lubiecki et al., 2007). Those who had surgery showed hyposensitivity to touch, cold, and heat in the region of the surgery, and subtle abnormalities in everyday sensations. In contrast to these long-term changes, Andrews and Fitzgerald (2002) found that infants who had abdominal surgery showed *hypersensitivity* to touch, both in the wound area and the contralateral side of the body in the first 24 postoperative hours. In another study, infants who underwent surgery in

the first 3 months of life, and then subsequent surgery in the same dermatome 15 (range 8–70; median: 10th–90th percentile) weeks later, needed more intraoperative fentanyl, had higher behavioural pain scores, had greater noradrenaline plasma concentrations, and needed more postoperative morphine than infants with no prior surgery (Peters et al., 2005). In contrast, in that study, infants who previously underwent surgery in a different dermatome had only higher postoperative analgesic requirements and noradrenaline plasma concentrations. These studies suggest spinal and supraspinal changes following early surgery. The long-term consequences of surgery in early infancy appear to be greater in areas of prior tissue damage, suggesting neurobiological changes with clinical implications for subsequent pain management. However, importantly no differences were found in heart rate, cortisol, or behavioural responses to vaccination in toddlers who had surgery early in life (Peters et al., 2003).

It is likely that effects of surgery will be related to age at surgery, the severity of the intervention, provision of effective pain management, how well surgery and the hospital stay were managed emotionally and cognitively for the young child, as well as the type and timing of subsequent evaluation. Taken together, it appears that early surgery can induce changes in peripheral and central tactile and pain processing; however, the direction, magnitude, and nature of the functional impact depend on multiple factors. In some of these studies samples of infants born preterm and full-term were combined. It is unknown whether physiological and brain maturity at the time of surgery (i.e. varying duration of gestation) contributes to the long-term impact on later pain threshold. Moreover, very preterm infants who undergo neonatal surgery also have been exposed to multiple other invasive procedures due to their prematurity. Studies on effects of early surgery on sensitivity to pain later in childhood that account for multiple sources of early pain experience during hospitalization are needed to uncover differences between infants born preterm and full-term.

## Burns

Children who had suffered burns early in life (at 6–24 months), displayed altered mechanical and pain sensitivity later in childhood at age 9 to 16 years, that varied by severity of the initial injury (Wollgarten-Hadamek et al., 2009). Compared to controls, children with moderate burns in infancy showed higher mechanical detection thresholds (hyposensitivity), lower mechanical pain thresholds (hypersensitivity), and greater sensitization to repetitive mechanical stimuli; however, no significant changes were found for thermal stimuli. In contrast, compared to controls, severely burned children showed elevated thermal pain thresholds, whereas mechanical pain sensitivity was not consistently different. The authors concluded that this differential pattern of altered sensory and pain sensitivity may reflect differences in stress, pain, and analgesic treatment between moderately and severely burned infants. Importantly, early traumatic and painful injuries, such as burns, can induce global long-term alterations in tactile and pain processing.

## Neonatal pain in preterm infants

Very preterm infants born 2 to 4 months before their due date spend weeks to months in the neonatal intensive care unit (NICU), outside the protective intrauterine environment. During this time the synaptic connections, integrated circuits, and descending modulatory

endogenous controls are immature (Fitzgerald and Walker, 2009), and pain induces diffuse activation across multiple brain regions (Fabrizi et al., 2011) therefore preterm infants are potentially most susceptible to pain and long-term effects of pain during the developmental period corresponding to the late second and entire third trimester of fetal life. Preterm neonates display lower thresholds (i.e. are more sensitive) and greater reflex responses to peripheral stimuli compared to full-term infants (Fitzgerald and Beggs, 2001). With repeated stimulation, reflex thresholds may drop even further (see Walker and Baccei, Chapter 6, this volume, for details of peripheral and central mechanisms of reflex sensitization). Importantly, sensitization to repeated tactile stimulation is greatest below 33 weeks postconceptional age (Andrews and Fitzgerald, 1994). Due to altered touch thresholds and sensitization, even non-invasive handling such as diaper change can elicit pain-like behavioural and autonomic responses in very premature infants, if the diaper change follows blood collection even after a 30-min rest period in between the procedures (Holsti et al., 2005). Similarly, when diaper change preceded blood collection, pain response to heel lance was heightened compared to blood collection after at least 1 h undisturbed (Holsti et al., 2006). In this way, sensitization may provide one mechanism whereby repetitive pain and handling lays the groundwork for ongoing pain and discomfort during neonatal intensive care.

## Later pain thresholds

Evidence for long-term effects of neonatal pain on later tactile and pain perception has now been demonstrated in multiple studies. Whereas the early work on long-term effects of neonatal pain on later pain sensitivity utilized parent report (Grunau et al., 1994a) or pictures (Grunau et al., 1998), more recent studies have directly compared behavioural and autonomic pain responses in infants born very preterm compared to healthy infants born at full-term. Findings differ depending on age at testing. Contrary to expectation, after hospital discharge, preterm infants showed little difference in reactivity to pain at 4 months corrected age (CA), either to a pain-naïve site of finger lance (Oberlander et al., 2000), or to more intense pain of immunization injections (Grunau et al., 2010). However, at 8 months CA, pain responses diverged in that the preterm group showed brief initial facial hyperresponsiveness to a finger lance, followed by faster behavioural and heart-rate recovery (Grunau et al., 2001). This rapid dampening evident at 8 months CA may underlie the appearance of reduced pain response to everyday bumps, scrapes, and falls reported by parents of preterms born at 800g or less compared to full-term toddlers (Grunau et al., 1994a). Differences may emerge across time, as reported in animal studies (e.g. Ren et al., 2004; see also Walker, Chapter 3, this volume).

At later ages, detection and pain thresholds for thermal, mechanical, and pressure stimuli have been studied, providing converging evidence of altered sensation in children born preterm. Pressure points were tested with a dolorimeter to measure later pain threshold, revealing that adolescents born preterm had more tender points and lower pain threshold (Buskila et al., 2003). Using quantitative sensory testing, both hyperreactivity (enhanced sensitivity) and hyporeactivity (reduced sensitivity) to pain have been reported at ages 9 to 14 years in children born preterm compared to full-term. The direction and the extent of effects varied depending on the type of pain stimulus and whether the pain was short-lasting or ongoing (Hermann et al., 2006; S. M. Walker et al., 2009). Preterms

and full-terms exposed to NICU care both differed from full-term healthy controls displaying increased baseline thermal thresholds (i.e. reduced sensitivity), but a greater degree of sensitization following prolonged heat at non-injured sites, suggestive of central changes. Findings of both baseline hyporeactivity but hyperreactivity to a noxious stimulus in these human studies are consistent with the animal literature on long-term effects of early pain (Ren et al., 2004; see also Walker, Chapter 3, this volume).

Importantly, the study of preterm infants born at less than 26 weeks of gestation (S. M. Walker et al., 2009) was the first to differentiate those who had neonatal surgery. While there were generalized differences between the children born preterm compared to full-term in heat and cold thresholds and also in response to mechanical stimulation adjacent to scars, it was the preterms that had neonatal surgery that primarily accounted for those findings. While the extent of tissue damage may be the most salient difference in those extreme preterms micropremies exposed to surgery, it is also possible that those requiring surgery may have been sicker and may have been exposed to more cumulative procedural pain during their NICU care. Further research is needed to elucidate the role of neonatal surgery in the long-term effects of altered pain thresholds in children born extremely preterm.

Using functional magnetic resonance imaging (fMRI) while children were exposed to pain stimulation, children born preterm showed greater cortical and subcortical brain activation (Hohmeister et al., 2010). In response to heat stimuli of moderate pain intensity, preterm but not full-term children that had required NICU care as neonates, exhibited significant activations in a number of brain regions (thalamus, anterior cingulate cortex, cerebellum, basal ganglia, and periaqueductal grey) that were not significantly activated in non-NICU exposed full-term controls. Moreover, the preterms showed significantly greater activation than controls in primary somatosensory cortex, anterior cingulate cortex, and insula. This exaggerated brain response in preterms was pain-specific.

### Recurrent pain in the long run: children, adolescents, and young adults

Self-report is considered the 'gold standard' for pain assessment. Surprisingly, given the altered sensory thresholds described earlier, there have been several reports that adolescents and young adults born preterm report few if any differences in recurrent pain in daily life compared to their peers born healthy at full-term (Buskila et al., 2003; Saigal et al., 1996, 2007; Schmelzle-Lubiecki et al., 2007; S. M. Walker et al., 2009). However, given the high prevalence of abdominal pain, headaches, limb pain, and other non-specific pain complaints in children in the general population, it is difficult to evaluate differences in these relatively small studies. Similarly, by parent report, greater somatization (functional pain complaints with no medical explanation) was more common in young preterm children at age 5 years (Grunau et al., 1994b; Sommerfelt et al., 1996); however, in a longitudinal cohort these differences were no longer apparent in later childhood at age 9 years (Whitfield et al., 1997) or in late adolescence at 17 years (Grunau et al., 2004a). Thus, although touch and pain thresholds differ in children born preterm, and brain activity in response to pain differs in preterms, contrary to expectations, there is little evidence at this point for long-term functional pain problems that impact daily life. However, further research is needed to evaluate gender differences in the emergence

of pain problems in adulthood, and the role that environmental life stresses may play in this population.

### Neurodevelopment

Infants born very preterm spend weeks to months in the NICU during a period of extremely rapid brain development and programming of stress systems, rendering them far more vulnerable to environmental perturbations such as neonatal pain, than infants born at term. For the tiniest, most fragile infants, the period of pain exposure is prolonged, during the last trimester of 'fetal' life, a time of very complex and rapid brain development. Neurodevelopmental problems including cognitive, language, visual-perceptual, visual-motor, attention and learning deficits as well as motor dysfunction are common in children born prematurely (e.g. Allen, 2008; Grunau et al., 2002), persisting to adulthood (e.g. Hack et al., 2002; Grunau et al., 2004a). Two mechanisms have been identified that may potentially link neonatal pain exposure to altered neurodevelopment in this vulnerable population, namely changes to the developing brain and programming of stress systems. It is known that immature neurons are more sensitive to neurotoxic environmental influences (see Lagercrantz et al., 2010). Atypicalities in structural and functional brain development are evident in preterm infants (e.g. Ment et al., 2009, S. P. Miller and Ferriero, 2009), however the causes are unclear.

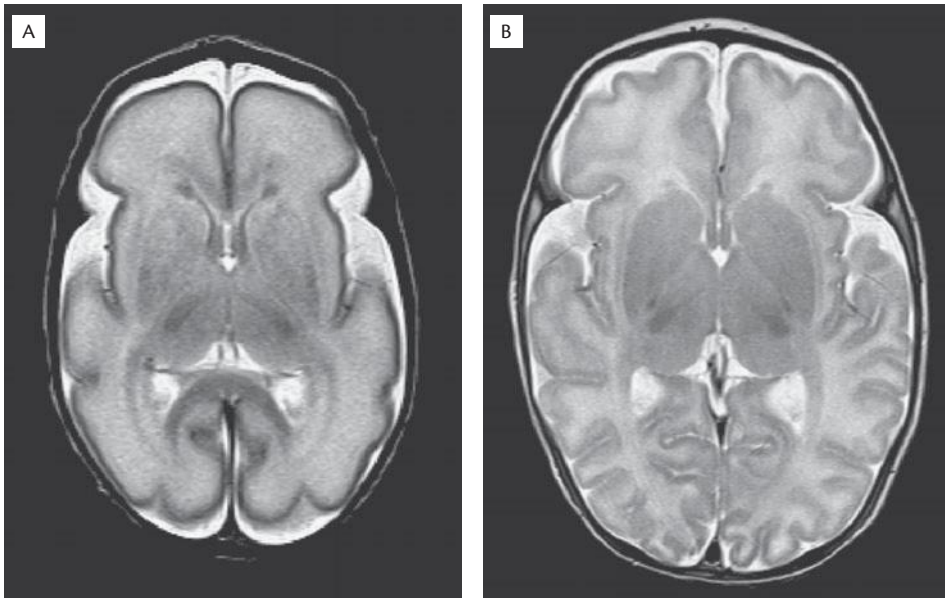

Greater neonatal pain exposure, defined as the cumulative number of skin-breaking procedures from birth to term equivalent, was found to be associated with poorer motor and cognitive development to 18 months CA, after adjusting for medical neonatal confounders (Grunau et al., 2009). This is consistent with evidence in another longitudinal cohort that repeated neonatal pain was associated with alterations in the developing preterm brain (Brummelte et al., 2012). Furthermore, prolonged exposure to repeated neonatal pain in preterm infants appears to contribute to altered programming of the hypothalamic-pituitary-adrenocortical (HPA) axis across the first 2 years of life (Grunau et al., 2004b, 2007), which has important implications for brain function.

### Pain and the immature developing brain

#### Brain reactivity to procedures

The brain undergoes very rapid developmental changes in macrostructure, microstructure, and connectivity during the time that infants born extremely preterm are undergoing neonatal intensive care. An example of the progression of structural brain maturation from 28 weeks of gestation to term-equivalent age is shown in Figure 4.1. Magnetic resonance imaging (MRI) studies have revealed atypical brain development in neonates born very preterm, e.g. smaller volume of the brain and specific regions, abnormalities in white matter microstructure, reduced cortical thickness, disturbances of the thalamocortical system, and altered development of the cerebellum and other structures (e.g. see Ball et al., 2011; Volpe 2009; see also Poorun and Slater, Chapter 39, this volume).

There has been long-standing concern that procedures conducted as part of life-saving care of preterm neonates may adversely affect brain development. Thirty years ago, Perlman and Volpe (1983) reported that endotracheal suctioning affected neonatal cerebral blood flow. In recent years there have been a number of important studies of cortical activity during procedural intervention in the NICU, utilizing near infrared spectroscopy to examine cerebral blood flow and electroencephalography (EEG) to measure electrical

**Figure 4.1** Structural maturation of the developing brain in one preterm infant from 28 weeks (A) to term equivalent age (B) MRI images courtesy of Dr Steven Miller.

activity, demonstrating that blood collection evokes responses in the cortex (Bartocci et al., 2006; Fabrizi et al., 2011; Slater et al., 2006, 2010; Tombini et al., 2009; Vanhatalo et al., 2009). Fabrizi et al. (2011) reported increased incidence of widely dispersed non-specific neuronal bursts of EEG activity in response to touch and pain in preterm infants, rather than the typical focused-evoked somatosensory potentials, maximal at the central electrodes that were evident in full-term neonates. This study is very important for understanding the vulnerability of preterm neonates, as it underscores the sensitivity of the preterm neonate to both mechanical and nociceptive stimulation. This phenomenon of responses widespread across the brain contributes to understanding why diaper change can evoke as much behavioural and autonomic reactivity as blood collection in preterm neonates while in the NICU (Holsti et al., 2005). It is challenging to record specific brain activity in response to painful procedures in young infants, since even after excluding overt movement artefacts, tensing of muscles in the face and limbs may affect the signal, given the proximity of the motor and somatosensory regions of the cortex (Maimon et al., 2013).

In the only fMRI study of the brain during pain stimulation, at age 9 to 14 years children born preterm showed greater activation in the somatosensory cortex and several other brain regions compared to children born full-term with or without early hospitalization (Hohmeister et al., 2010; see also Hermann, Chapter 40, this volume). More research is needed to explicate relationships between brain, behaviour, and autonomic reactivity in the preterm neonate under various conditions across post-conceptual age in the NICU.

### Neonatal pain and brain development

Utilizing state-of-the-art brain imaging techniques to study microstructure development from early in life to term equivalent age, Grunau and colleagues found an association between greater exposure to pain-related stress in preterm infants in the NICU and poorer neonatal brain development (Brummelte et al., 2012). In a longitudinal design, serial MRI and diffusion tensor imaging was

carried out shortly after birth and again at term equivalent age in neonates born at 24 to 32 weeks of gestation. After adjusting for multiple clinical confounding factors, such as gestational age at birth, infections, brain injury, and surgery, higher exposure to procedural pain was associated with reduced development of white matter (indexed by fractional anisotropy (FA)) and subcortical grey matter (measured by N-acetylaspartate to choline ratio (NAA/choline)—a marker of cerebral metabolism and density). Reduced FA was predicted by early pain prior to the first brain scan, whereas lower NAA/choline was predicted by pain exposure throughout the neonatal course, suggesting a primary and early effect on subcortical structures with secondary white matter changes. This study appears to be the first in human infants to show that neonatal pain is associated with adverse brain development. Until now, relationships between pain and brain development in preterm infants were speculative.

In the first study to examine whether neonatal pain is associated with brain activity later in childhood, in a different longitudinal cohort of preterm infants followed from birth to school age, Grunau and colleagues found an association between greater cumulative neonatal pain and spontaneous oscillatory brain activity under resting conditions using magnetoencephalography at age 7 years (Doesburg et al., 2013). In turn, the cortical activity was associated with cognitive function. Importantly, in this study the link between neonatal pain and brain function was evident in infants born extremely preterm at 24 to 28 weeks, but not in more mature preterm infant born 29 to 32 weeks. It is well established that there are progressive changes in the maturation of oscillatory brain activity throughout the preterm period, as shown in the spectral composition of EEG recordings (Okumura et al., 2003). The finding that neonatal pain was associated with brain activity in infants born at 24 to 28 weeks, but not later, may reflect the distinct phases of development occurring within thalamocortical systems within the 24- to 28- and 29- to 32-week gestational periods, and the implications for how pain is processed within the developing CNS (Kostovic and Judas, 2010).

Furthermore, the findings described are consistent with reports that adverse early stress beyond pain exposure, such as maternal separation, is implicated in altered brain structure and function (Als et al., 2004; Milgrom et al., 2010; Smith et al., 2011). In one study (Als et al., 2004), preterm neonates were randomized to receive the Neonatal Individualized Developmental Care and Assessment Program (NIDCAP; Als, 1982) or standard care during their NICU stay. The NIDCAP programme involves recognition of infant stress cues and provision of supportive care. At 2 weeks CA, the infants that received the intervention programme displayed significantly better motor system functions and self-regulatory behaviours, as well as increased coherence between frontal and a broad spectrum of primarily occipital brain regions on electrophysiological testing (Als et al., 2004). Furthermore improved behavioural function was still apparent at 9 months CA. In another randomized controlled trial, effectiveness of training parents to reduce stressful experiences for their very preterm infants in the NICU was evaluated (Milgrom et al., 2010). At term equivalent, the stress sensitivity training was associated with fewer atypicalities in cerebral white matter microstructure and connectivity on advanced MRI, compared to infants that received standard care.

Taken together, these studies on brain reactivity to procedures, as well as associations between pain and brain development, begin to address the role that pain might play in contributing to altered spontaneous cortical oscillatory activity (within functionally distinct frequency ranges, theta (46–7 Hz), alpha (8–14 Hz), beta (15–29 Hz), and gamma (30–60 Hz) neuromagnetic activity (Doesburg et al., 2011a)) and atypical long-range neuromagnetic synchronization during visual short-term and working memory maintenance associated with alteration and reorganization of functional connectivity in children born very preterm (Doesburg et al., 2011b), as well as a host of atypicalities in structural and functional brain development revealed by MRI in children born very preterm (see Ment et al., 2009 for review). There is now converging evidence that the developing brain is exquisitely sensitive to ongoing procedural perturbations during a ‘critical window’ in early life, suggesting that the long-term effects of pain are potentially greatest in extremely preterm infants during hospitalization in the NICU.

### Programming of stress systems

Altered programming of stress systems, including the HPA axis, due to both fetal and neonatal stress is well established in the animal literature (e.g. Matthews, 2002), and in humans in studies of post-traumatic stress disorder (G. E. Miller et al., 2007) or early adversity such as institutional care in orphanages (Loman and Gunnar, 2010). Unexpectedly, in animal studies of long-term effects of early pain, no changes were found in HPA responses later in adult rats (Anand et al., 1999; C. D. Walker et al., 2003). Importantly, C. D. Walker et al. (2003) showed that following pain, maternal licking and grooming increased, thus preventing changes to the stress hormone system. In preterm infants, exposure to repeated neonatal pain in the NICU is typically combined with the stress of maternal separation. The developmental trajectory of the expression of cortisol (the endpoint of HPA axis activity) appears to be altered across the first 2 years of life in infants born at extremely low gestational age (24–28 weeks), with downregulation extending from the NICU period (Grunau et al., 2005) switching to upregulation at 8 and 18 months CA (Grunau et al., 2004b, 2007), associated with greater exposure to procedural pain.

### Sleep

Sleep–waking states develop during the third trimester of fetal life, and thus are emerging during the period that preterm infants are exposed to repeated procedural pain in the NICU. There is long-standing interest in effects of sleep disruption on the developing CNS (e.g. Anders and Roffwarg, 1973; Scher et al., 2005). Sleep plays an essential role in brain development (Blumberg and Seelke, 2010). Shifts in sleep state occur in response to pain in the NICU, thus have become a key part of pain assessment (e.g. Holsti et al., 2008; Stevens et al., 2010), however little is known about effects of pain and pain management on sleep in preterm neonates. Importantly, opioids for pain management affect sleep structure, for example, decreasing rapid eye movement sleep (Axelin et al., 2010). Fabrizi et al. (2011) reported that the occurrence of noxious-specific EEG potentials was not state dependent, since the proportion of awake infants was the same for those who did and did not exhibit the noxious-specific EEG response. However, very preterm infants typically spend little time awake in the NICU. Further EEG and behavioural studies of effects of pain on sleep are needed, to elucidate the role of pain in preterm infants on brain development via disruption of sleep.

### Sex and gender

Sex refers to biological and physiological characteristics, whereas gender is defined as the socially constructed roles, behaviours, activities, and attributes that a given society considers appropriate for men and women (World Health Organization, 2012). Sex differences in long-term effects of early pain and stress are widely reported in the animal literature (Laprairie and Murphy, 2007), and gender differences in adult pain experience are well-established (Unruh, 1996). However, in human clinical studies of long-term effects of early pain, sex and gender differences have rarely been examined. In a longitudinal cohort no differences were found between boys and girls in cortisol levels during infancy and toddlerhood (Grunau et al., 2004b, 2007). Contradictory findings have been reported, for example, in one study girls displayed greater pain sensitivity than boys among both preterm and full-term adolescents (Buskila et al., 2003). In a cohort of micropremies (S. M. Walker et al., 2009) term control boys were more sensitive than girls to cold and heat stimulation, but no gender differences were found in the preterm group. More research with larger sample sizes is needed to explicate the role of gender, and possible interactions with environmental caregiver factors.

### Caregiver behaviour and long-term effects of neonatal pain

Setting the foundation for optimal infant support to minimize pain-related stress begins in the NICU. Nursing interventions during procedures, and teaching parents how to read their infant’s cues and how to provide environmental support such as skin-to-skin contact, swaddling, and facilitated tucking is likely to be fundamental in helping the infant to gradually self-regulate stress (Feldman et al., 2002; Maroney, 2003; Symington and Pinelli, 2006). Importantly, parent involvement to reduce infant stress in the NICU led to improved behaviour and EEG coherence (Milgrom et al., 2010).

Social modelling, family factors, child temperament, culture, and gender affect pain expression and thereby pain threshold later in

childhood and beyond. This body of work has been conducted primarily on full-terms (e.g. Braarud and Stormak 2006; Moon et al., 2008; Piira et al., 2007; Pillai Riddell and Chambers, 2007). Parent soothing is associated with greater reactivity, not less, whereas verbalizations that promoted coping reduce pain responses in infants undergoing immunization. Little research after NICU discharge has addressed whether parent behaviours across infancy and childhood may ameliorate or exacerbate effects of early pain on later pain sensitivity or on neurodevelopment in children born preterm exposed to prolonged pain early in life. Greater parenting stress appears to compound the association between higher neonatal pain exposure and poorer cognitive development at 18 months in children born very preterm (Grunau et al., 2009). However, since poorer neurodevelopment in preterm children is in turn associated with persisting parenting stress (Brummelte et al., 2011), it is difficult to disentangle these effects. Among infants with extensive history of exposure to neonatal pain in the NICU due to extremely preterm birth, child and family factors predicted somatization at age 4 years (Grunau et al., 1994b). In another study, at age 9 to 14 years, maternal factors in relation to responses to quantitative sensory testing of pain thresholds were compared in three groups of children: those born preterm who had been in the NICU, full terms who had been in the NICU, and full-term healthy controls (Hohmeister et al., 2009). Threshold testing was conducted with and without the infant's mother present. Only former preterms displayed more catastrophizing and elicited greater maternal solicitous responses to pain. Importantly, mother presence led to higher pain thresholds (reduced sensitivity) in all groups.

Major gaps in knowledge include whether parent involvement in NICU care can prevent effects of neonatal pain on brain development, and whether in the long term, parent stress, anxiety, and other factors across childhood may exacerbate effects of pain exposure early in life in vulnerable infants. The extent to which sensitive parenting may ameliorate effects of neonatal pain, and whether gender has differential effects, is also unknown.

## Conscious awareness and adverse effects of pain

Accepted definitions of pain as a phenomenon involving a complex interplay of sensation and cognition are adult focused, and may not capture fundamental characteristics of the developing organism. Based on this adult orientation, attempts to understand when the fetus and neonate might become consciously aware have been used to determine when pain might be perceived. Conditioned learning is evident early in life even during sleep (Fifer et al., 2010)—implying memory presumably without conscious recall. Moreover, behavioural evidence of conditioning, as well as evoked EEG and physiological responses after pain underlie 'biological memory'. Thus, although infants cannot recall early experiences, the CNS appear to retain 'memory' that is manifested later in altered responses to pain in new situations (Grunau, 2003; Taddio et al., 1997).

Recent evidence suggests that the long-term impact of pain on later brain function differs depending on the biological maturity of the infant and the stage of underlying brain development at the time of hospitalization (Doesburg et al., 2013). In the case of extremely premature birth (see case example), effects of repetitive procedural pain-related stress on the vulnerable developing brain and stress

systems likely occur irrespective of conscious awareness. Thus, consideration of the distinction between *nociception* and *pain* may be helpful in elucidating long-term impacts on different systems.

It has been proposed that conscious perception of pain is required for pain to impact the individual (e.g. Lee et al., 2005). This has led to a focus on the topic of when consciousness emerges in during fetal life, which has implications for intrauterine interventions as well as treatment of infants born very preterm. However, biological processes initiated by nociception stimuli can impact the organism regardless of conscious awareness. Even extremely preterm neonates born at 24 weeks of gestation display sensitization to skin-breaking stimulation, which is a basic physiological phenomenon of the immature organism's hypersensitivity to tactile inputs, together with limited capacity to regulate excitatory and inhibitory systems (Andrews and Fitzgerald, 1994; Fitzgerald, 2005). Thus, nociceptive reactivity can be altered due to changes at the spinal cord level. Similarly, altered stress hormone levels associated with repetitive exposure to neonatal procedures do not have to involve higher order consciousness to induce short- and long-term effects. These altered systems are signs of implicit biological memory, and the processes engaged can alter the CNS and stress physiology without any conscious perception of pain. Pain, on the other hand, is defined as a complex response engaging both emotional and nociceptive responses. This distinction between nociception and pain is important in considering long-term effects of procedural events in neonates and young infants. This distinction does not rule out the possibility that higher-order cortical regions of the brain may be engaged in relation to procedures early in infancy, but rather removes the idea that conscious perception of pain is a requirement for a long-term impact to take place. Specifically, nociceptive response can initiate a physiological cascade of events that directly or indirectly impacts the brain and stress development of very preterm neonates, *regardless of whether they perceive pain consciously*.

## Conclusion

Long-term effects of early pain on later pain and tactile sensitivity are complex, and depend on multiple factors such as age at pain stimulation, extent of tissue damage, type of noxious insult, intensity, duration, and age. Recent studies show that neonatal pain evokes changes in brain activity, providing important clinical evidence that the behavioural, autonomic, and hormonal responses to procedures in infants go beyond defensive reflexes. Advanced imaging techniques have revealed that neonatal pain in preterm infants is associated with altered brain development during the neonatal period in very preterm infants, for the first time providing clinical evidence of mechanisms that may underlie the emerging association between cumulative procedural pain exposure and neurodevelopment and behaviour in children born very preterm.

Probably the most unexpected finding in recent years has been convergent evidence from several countries showing that, despite the impact of early pain on somatosensory processing and pain sensitivity, self-reported everyday pain problems do not appear to be more pronounced in late adolescence or early adulthood following exposure to extensive pain in the neonatal period. However, long-term studies are needed to evaluate whether under life stresses over time, differentially by gender, pain syndromes may develop later.

**Case example: long-term impact of pain in preterm twin girls**

As part of a longitudinal programme of research in long-term effects of neonatal pain in preterm infants born at 24 to 32 weeks of gestation, non-identical twin girls (here referred to as Iris and Betty—not their real names) participated in studies in the NICU, and at ages 3 months, 8 months, 18 months, and 7 years. The twins were born at 29 weeks of gestation with birthweight appropriate for their gestational age, and similar size at birth, but had different neonatal experiences that illustrate divergent trajectories of early pain and outcomes. Betty had 75 skin-breaking procedures from birth to term equivalent while Iris had 111; neither girl underwent surgery. The most striking discrepancy in outcome between the sisters was that at age 7 years, when Betty's cognitive functioning was above average with verbal comprehension and perceptual reasoning at the 95th and 97th percentiles respectively, whereas Iris had scores significantly lower than her sister, with verbal comprehension at the 45th percentile and a deficit in perceptual reasoning at the 4th percentile. In addition, Iris was below age expectation in planning and problem solving aspects of executive functioning. Despite these low scores, in second grade Iris copes with early reading and arithmetic, displaying compensation for her difficulties with aspects of cognitive abstraction. This capacity to compensate is consistent with the finding that very preterm children engage different brain networks reflecting brain plasticity over time (Doesburg et al., 2012), despite the association between neonatal pain and early brain development while in the NICU from birth to term (Brummelte et al., 2012). There are numerous confounding factors that obscure potential effects of neonatal pain per se in hospitalized infants, therefore it is important that neither of the children had any infections in the neonatal period, received no postnatal steroids, and that Betty underwent no mechanical ventilation and Iris only needed it for 4 days. Given that the twins grew up in the same family and broader social environment, the difference in skin-breaking neonatal events appears to be a salient factor that may have contributed to their differences in cognitive outcomes; however, clinical research alone can only establish associations, not causality. In addition, as non-identical twins, their genetic make-up differs. Another avenue of future investigation is to uncover what genetic factors may render some infants more vulnerable to pain-related stress early in life, and what genetic factors may be protective.

## CHAPTER 5

---

# Prevention of the development and maintenance of paediatric chronic pain and disability

M. Gabrielle Pagé, Anna Huguet , and Joel Katz

### Summary

Understanding the predisposing factors that confer a greater risk of developing chronic pain is an essential step in pain prevention and management. This chapter focuses on current theoretical models that can inform prevention of paediatric pain and disability. We review the literature on known risk/protective factors, markers, correlates, and prognostic factors for the transition to chronic pain and disability across a variety of pain conditions. We distinguish between primary, secondary, and tertiary levels of pain prevention and discuss the clinical implications of this distinction.

### Introduction

Estimates of paediatric chronic pain (i.e. pain that continues past the usual tissue healing time—typically 3 months) range between 15% and 30% (Bandell-Hoekstra et al., 2001; Perquin et al., 2003). The consequences of poorly managed acute and chronic pain are potentially quite significant. Unrelieved pain is associated with medical (medical complications, longer hospital stay, higher risk of infections), physiological (neuroplasticity, sensitization, increased risk of chronic pain), psychological (distress), and socioeconomical (increased health care costs) consequences (Aasvang and Kehlet, 2007; Anand et al., 1987; McCaffery, 1977). Among children who report experiencing chronic pain for more than 3 months, between one-half and two-thirds continue to report chronic pain 1 and 2 years later, respectively (Perquin et al., 2003).

The mechanisms underlying the transition from acute to chronic pain are not fully understood. It is likely that they involve a combination of biopsychosocial, behavioural, and physiological components (Priest and Hoggart, 2002). Identifying risk factors for the development of chronic pain can lead to preventive programmes including treatment before the pain begins, or before it has become chronic. This would help prevent the processes that are involved in the development and maintenance of chronic pain.

In this chapter, we focus on the biological and psychological factors associated with the development of paediatric chronic

pain. We define and identify risk/protective factors, predictors, correlates, markers, and prognostic factors across pain conditions, describe three types of pain prevention, review current theoretical models of the development and persistence of pain, and describe prevention strategies associated with identified correlates, markers, risk/protective, and prognostic factors.

### Correlated factors, risk/protective factors, markers, and prognostic factors

Preventing paediatric pain necessitates the identification of risk and protective factors from which risk levels for a child to develop pain can be determined. It also requires the identification of prognostic factors to better understand a child's probability of recovering from a chronic pain state. A risk factor is defined as a 'measurable characterization of each subject in a specified population that precedes the outcome of interest and can be used to divide the population into ... high-risk and ... low-risk groups' (Kraemer et al., 1997, p. 338). The temporal criterion of precedence is essential for a variable to qualify as a risk factor; otherwise it is a correlate. Similarly, a protective factor predicts a lower risk of the outcome (i.e. it protects against the risk). Risk and protective factors are both called predictors (i.e. without reference to sign). Predictors that cannot be modified are referred to as fixed markers (e.g. sex, race; Kraemer et al., 1997). A prognostic factor is a variable that provides information about the chances of recovery from, or recurrence of, a disease or condition. Thus, a risk or protective factor predicts the chances of developing or contracting a disease, whereas a prognostic factor predicts the outcome of a disease (recovery or recurrence once the disease has developed; Laupacis et al., 1994).

### Primary, secondary, and tertiary prevention of paediatric pain

Prevention of paediatric pain not only focuses on effectively managing and averting acute pain due to iatrogenic causes (e.g. from medical and surgical origins), but also on ensuring that acute pain

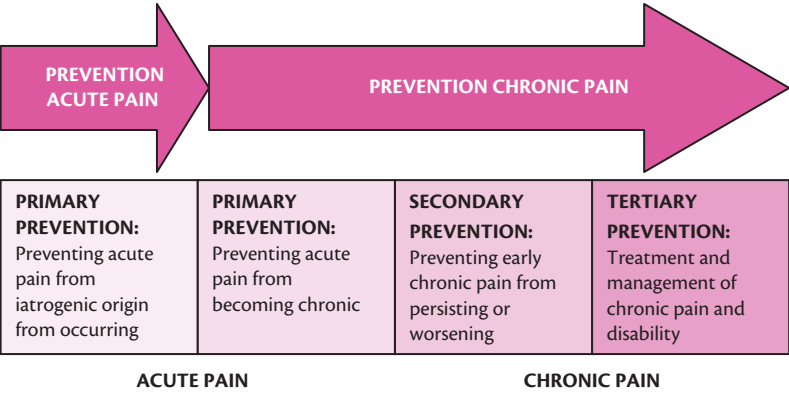

Figure 5.1 Primary, secondary, and tertiary prevention of paediatric pain.

does not become chronic and disabling. It is essential to develop intervention strategies that target these various forms of prevention, namely primary, secondary, and tertiary (see Figure 5.1).

Preventing acute pain of iatrogenic origin

Preventing acute pain generally refers to the anticipation and avoidance of pain onset. Complete prevention of acute pain is not desirable; children learn coping skills and safety behaviours from experiencing minor cuts, bruises, scrapes, etc. Many efforts have been made, through programmes such as Safe Kids USA and Safe Kids Canada to prevent serious injuries and traumas and indirectly prevent children from experiencing pain. While these programmes are examples of primary prevention, they will not be reviewed here given the lack of a pain-specific focus. Rather, the focus will be on acute pain from invasive medical and surgical procedures, as it can have long-lasting consequences including preprocedural anxiety, hyperalgesia, avoidance of health care, development of chronic pain, and disability. Prevention of acute pain of iatrogenic origin relies on neutralizing the risk factors associated with the onset of acute pain. Interventions that decrease the risk of developing acute pain are amongst the most cost-effective in managing pain.

Preventing the development and maintenance of chronic pain

Primary prevention refers to the early identification of acute pain and management strategies to ensure the pain does not become chronic. Identification of risk factors for chronic pain and intervention strategies aimed at modifying these factors when the pain is acute are strategies associated with primary prevention of chronic pain.

Secondary prevention consists of preventing early chronic pain states from worsening or persisting. Identification and modification of prognostic factors with the aim of reducing or eliminating the chronic pain experience are examples of secondary prevention strategies.

Tertiary prevention refers to the reduction of pain-related disability and impairment, as well as the improvement of quality of life. Tertiary prevention also focuses on identifying and removing barriers to treatment, facilitating treatment adherence, and improving adaptive daily functioning.

Until recently, the lack of a paediatric pain-related disability or pain interference tool has hindered research on tertiary prevention. The Functional Disability Index (FDI; Walker and Green,

1991) is widely used to evaluate functional disability in children with chronic pain; however, the source of disability is not specified in the FDI. This lack of specificity may impede efforts aimed at reducing pain-related disability or at validating theoretical models of paediatric pain-related disability. Other pain-specific and often population-specific scales, such as the Child Activity Limitations Interview (CALI; Palermo et al., 2004), the PROMIS Pediatric Pain Interference Scale (Varni et al., 2010), the Pediatric Migraine Disability Assessment (PedMIDAS; Hershey et al., 2001) can be used by clinicians and researchers to assess the extent to which the pain per se contributed to the child’s disability. Future research directions include the evaluation of theoretical models of pain-related disability using these scales as well as examination of the convergent validity of global functional and pain-related disabilities.

Theoretical models and theories

Prevention of chronic paediatric pain relies on the identification and appropriate modification of empirically validated causal risk, protective, and prognostic factors. A critical examination of current theoretical models may help in the search for factors that can ultimately be used in preventing paediatric chronic pain (see also Pillai Riddell et al., Chapter 9, this volume).

The causal risk and protective factors, and hence, the mechanisms underlying the transition from acute to chronic pain and the maintenance of chronic pain likely involve a combination of various components (e.g. biological, psychological, sociocultural, genetic). Although some researchers have proposed theoretical models of the development and persistence of paediatric pain (Palermo and Chambers, 2005) most have been developed either for adult pain populations or are paediatric models not specific to chronic pain. The dominant models are summarized as follows.

The *operant conditioning model* (Fordyce et al., 1968) posits that pain behaviours are influenced by a system of punishment, reinforcement, and extinction. It also stipulates that pain behaviours may become independent of physiological and sensory elements and occur in response to external reinforcement contingencies. The *fear-avoidance models of pain* (Asmundson et al., 2004; Leeuw et al., 2007; Vlaeyen et al., 1995) illustrate the relationships among pain-related catastrophic thinking, pain-related fear/anxiety, and pain perception. In the absence of pain-related fear, symptoms of pain are confronted, leading to recovery. Alternatively, when pain symptoms are interpreted catastrophically, pain-related fear and anxiety

reactions ensue, followed by avoidance behaviours and hypervigilance of somatic symptoms, in particular pain, followed by disuse, disability, and depression, which in turn feed back into the pain experience to fuel pain-related fears in a never-ending cycle. The recently developed *paediatric fear-avoidance model of chronic pain* (Asmundson et al., 2012) adds to the adult fear-avoidance model child/adolescent factors and parental variables that contribute to the development and maintenance of chronic pain. More specifically, parental pain management behaviours (e.g. protectiveness, solicitousness) and child psychological responses (e.g. catastrophizing, acceptance) will interact and influence child psychological response and escape/avoidance behaviours (Asmundson et al., 2012). The *diathesis-stress model of chronic pain and disability* (Turk, 2002) explains the progression from acute pain following an injury/trauma to chronic disabling pain in adults. The model stresses several constructs as major predictors of the development of chronic pain and the maintenance of disability: (1) a predisposing factor: anxiety sensitivity; (2) cognitive processes: fear of further pain and harm, catastrophizing cognitions, and low self-efficacy; and (3) operant processes. A modification of the model to include symptoms of post-traumatic stress disorder has received empirical support in patients before (Martin et al., 2010) and after (Kleiman et al., 2011) surgery.

The *integrative model of parent and family factors in paediatric chronic pain and associated disability* (Palermo and Chambers, 2005) emphasizes the importance of parents and family to understand the child's pain experience and specifically suggests three interrelated levels of factors that influence pain and disability: (1) individual factors (e.g. parental behaviours), (2) parent-child interactions, and (3) family-related variables (e.g. familial environment).

The *biopsychosocial model of pain* (Engel 1977; Gatchel et al., 2007; Turk, 1996) posits that 'pain' is a subjective idiosyncratic experience that includes biological (e.g. autonomic, endocrine, and immune systems, genetic predispositions), psychological (e.g. fear, anxiety, previous pain experiences), and social (e.g. cultural and familial) aspects. The *perceived self-efficacy model of chronic pain* (Bursch et al., 2006; Vuorimaa et al., 2008) states that beliefs about one's ability to cope with pain and to maintain everyday life activities despite pain will impact one's regards towards pain control, pain coping, and daily functioning, which in turn regulates pain and associated disability. The *modelling/social learning theory* (Bandura, 1986; Craig and Prkachin, 1978) emphasizes the important role of modelling; that is, the capacity to learn a wide range of behaviours, such as complex pain behaviour patterns, through observation of pain behaviours of others. The potency of modelling as a method of learning can be enhanced by the consequences (reinforcement or punishment) of the modelled behaviour, the consequences that meet the imitative behaviour adopted from the model, the expectancies of one's abilities to execute the modelled behaviour, and the outcome expectancies of future consequences. Last, the *attachment theory* (Bowlby, 1973) when applied to pain suggests that pain serves as a signal of threat and consequently activates a sequence of attachment behaviours, which in turn will influence the pain experience.

## Specificity of pain models

Most models described have not been evaluated in children although there is support for various components (see Table 5.1).

Taken together, these results suggest the models are relevant to the paediatric population but important components remain to be tested in children and adolescents.

Research has been slow to identify factors responsible for the development and maintenance of chronic pain and disability in children. This is in part because of: (1) the relative absence of theoretical models conceptualized (or adapted) specifically for paediatric populations, (2) the heterogeneity of pain outcomes assessed by current adult theoretical pain models, and (3) the absence of empirically validated questionnaires to measure constructs relevant to specific models. While it is clear that factors identified in the following section are associated with paediatric pain, they have been mainly examined in isolation from one another. Remediating this lack of an integrative framework might be a necessary subsequent step through which underlying mechanisms can be identified (Huguet et al., 2011).

Importantly, as mentioned earlier, the primary outcome of interest differs from one model to the other (e.g. pain behaviours, pain experience, chronic pain, and disability). Predictor variables in one study are commonly used as outcome measures in other studies and vice versa, reflecting the complexity of the problem and the variety in hypothesized mechanisms (Katz, 2012). As such, these differences must be taken into account when creating integrative models of chronic pain. One of the challenges is to develop sufficiently broad models of the factors hypothesized to be associated with chronic pain outcomes. Recent advances in the quality of clinical research are due in large part to recommendations regarding assessment of core domains of functioning (Turk et al., 2003); the issue of the most appropriate measure with a given domain however, remains to be determined (Turk et al., 2008). Core outcome domains that have been recommended to be included in paediatric clinical trials include pain, physical functioning/physical recovery, emotional functioning, role functioning, patients' satisfaction with treatment, symptoms and adverse events, sleep, and economic factors (McGrath et al., 2008). This type of integrative research is essential to the elaboration of testable hypotheses about underlying mechanisms of paediatric chronic pain and disability, leading to the elaboration of prevention strategies.

## Common correlates, predictors, markers, and prognostic factors of chronic pain and disability

The literature has focused mostly on finding correlates of chronic paediatric pain using cross-sectional studies and only more recently on finding risk/protective and prognostic factors associated with the onset and course of paediatric chronic pain. The factors that have been more commonly explored through a cross-sectional or longitudinal design are: (1) demographic characteristics (i.e. gender and age; Egger et al., 1998; Sjolie, 2002; Vikat et al., 2000), (2) health status (e.g. Vikat et al., 2000), (3) anthropometric characteristics (Kovacs et al., 2003; Sjolie, 2002), (4) physical conditions (Kovacs et al., 2003), (5) mechanical characteristics (Bejia et al., 2005; Jones et al., 2003), (6) sleep problems and physical activity (Laurell et al., 2005; Vikat et al., 2000), and (8) smoking (Kovacs et al., 2003).

In addition, the following factors have been studied as potential correlates, predictors, markers or prognostic factors of paediatric pain-related disability: (1) demographic characteristics (i.e. age and sex; Konijnenberg et al., 2005; Logan and Scharff, 2005);

**Table 5.1** Empirical support for pain and pain-related disability models in paediatric populations

Outcome	Predictors						
	Person-centred models			Systemic models			
	Operant	Diathesis	Fear-avoidance	Biopsychosocial	Perceived self-efficacy	Social learning	Attachment theory
<b>Chronic pain</b>		<b>Anxiety sensitivity</b> (Tsao et al., 2009) <b>Pain-related fear and pain anxiety</b> (Simons et al., 2011) <b>Pain catastrophizing</b> (Crombez et al., 2003; Vervoort et al., 2006) <b>Self-efficacy</b> (Bursch et al., 2006; Vuorimaa et al., 2008)		<b>Biological</b> (e.g. age, gender, genetic factors) (El-Metwally et al., 2008; Hechler et al., 2010; Martin et al., 2007b) <b>Psychological</b> (e.g. coping, distress) (Gauntlett-Gilbert and Eccleston, 2007) <b>Social</b> (e.g. family, parental response) (Logan and Scharff, 2005)	<b>Perceived self-efficacy</b> (Bursch et al., 2006; Vuorimaa et al., 2008)	<b>Punishment reinforcement expectancies of modelling</b> (Allen and Shriver, 1998; Minuchin et al., 1975)	<b>Attachment style</b>
<b>Disability/disuse</b>			<b>Pain catastrophizing</b> (Crombez et al., 2003; Lynch et al., 2006; Vervoort et al., 2006) <b>Pain-related fear and anxiety</b> (Martin et al., 2007a) <b>Pain-related fear and avoidance</b> (Wilson et al., 2011)		<b>Perceived self-efficacy</b> (Bursch et al., 2006)		
<b>Pain behaviours</b>	<b>Punishment reinforcement</b> (Allen and Shriver, 1998; Minuchin et al., 1975)						<b>Attachment style</b> (Walsh et al., 2008)

(2) general health status (Claar et al., 1999; Konijnenberg et al., 2005); (3) psychological characteristics such as depression, vulnerability, or psychological distress (Logan et al., 2006; Vervoort et al., 2006); (4) pain coping responses (Kashikar-Zuck et al., 2001; Sawyer et al., 2005); (5) catastrophic thinking (Kashikar-Zuck et al., 2001; Vervoort et al., 2006); (6) environmental contingencies to pain behaviours (Craig and Pillai Riddell, 2003; Van Slyke and Walker, 2006); and (7) parental or family characteristics including parental pain, parental distress, parental stress (Logan and Scharff, 2005). Recently, pain unpleasantness has been found to be associated with the transition from acute to chronic pain while anxiety sensitivity has been associated with the maintenance of chronic pain after surgery (Pagé et al., 2013).

Systematic reviews and meta-analyses will make it possible to identify the most important evidence-based factors that contribute to the development and course of paediatric pain and determine the specific and common factors associated with particular pain conditions (Huguet et al., 2011). At the moment, the most common factors that are considered to be correlates, predictors, markers or prognostic factors of paediatric pain are highlighted in Table 5.2, based on published reviews. The majority of these reviews, however, are non-systematic.

## Prevention strategies for paediatric pain

Prevention strategies can be classified into the following three domains: physical, psychosocial, and pharmacological. A combination of more than one approach will be optimal in preventing the development and/or maintenance of pain in children. As highlighted in the theoretical models previously described, sensory, cognitive, and affective factors are thought to interact to predict paediatric pain and disability. It follows, then, that pain prevention will also involve a multidisciplinary approach which will vary according to the level of intervention.

Whereas clinical pain management relies increasingly on multimodal approaches (e.g. pain management in neonates; Allegaert, 2009; Parry, 2011), research typically focuses on unidimensional aspects of pain prevention and management. A good example of this disconnect between clinical practice and research can be found in the literature on recurrent abdominal pain (RAP). Three Cochrane reviews focus on the tertiary prevention of RAP: one focuses on dietary management (Huertas-Ceballos et al., 2009), a second focuses on pharmacological interventions (Huertas-Ceballos et al., 2008a), and the third examines psychosocial interventions (Huertas-Ceballos et al., 2008b). Individually, these reviews provide important

**Table 5.2** Reviews of predictors of paediatric pain (systematic and non-systematic)

Pain condition	Authors	Outcome	Findings	
<b>Recurrent abdominal pain</b>	(Gieteling et al., 2011) <sup>a</sup>	Persistence of RAP	Predictors: prognostic factors, markers  Non-significant predictors, prognostic factors, markers: Unclear/still unknown:	High levels of negative life events High levels of functional gastrointestinal complaints in family Illness perception Female sex Behavioural disturbances Psychological disorders Severe abdominal pain. Young age Low educational level Depressive/anxiety disorders Self-perceived academic competence Long duration of abdominal pain History of two or more surgeries Presence of other associated symptoms (nausea, vomiting, headaches) High levels of functional disability Low socioeconomic status Attitude towards health care
	(Scharff, 1997)	RAP	Correlates, predictors, prognostic factors, markers:	Underlying physiological predisposition Dietary influences Anxiety Recent stressful events and coping abilities Family issues
	(Schulte et al., 2010)	Development of RAP	Predictors, prognostic factors, markers:	Abdominal inflammation processes Familiar genetic vulnerability to gastrointestinal symptoms and psychopathology Temperament Life events and stressors Psychopathological comorbidity
		Maladaptation to RAP	Predictors, prognostic factors, markers:	Maladaptive pain processing Maladaptive pain communication in the family Maladaptive coping style Psychopathological comorbidity

<sup>a</sup> Systematic reviews.

prevention and treatment approaches to childhood RAP, but they do not provide a comprehensive, multidisciplinary approach to the treatment of RAP nor do they provide insight into the effectiveness of combining, or the optimal combination of, various approaches. Methodological challenges and realistic constraints and costs associated with conducting multidisciplinary, multiple group studies may, in part, explain this lack of integrative research. Investigating the efficacy of separate interventions is a good first step in designing prevention and treatment programmes. But it is important to keep in mind that the outcome of such research results in isolated islands of knowledge and a lack of understanding of the optimal multidisciplinary treatment combination that would be most effective. The next step would be to conduct outcome research combining multiple interventions consisting of those that have been shown to be the most effective.

The non-modifiable factors identified earlier (e.g. age, sex) can help in identifying children at higher risk of developing pain and engage them in early prevention treatments. Most of the prognostic factors, predictors, and risk factors, however, are modifiable and intervention strategies should focus on minimizing the risk of developing pain or maintaining pain and pain-related disability associated with these factors.

## Primary prevention of acute pain of iatrogenic origin

Significant efforts have been deployed to prevent or reduce pain during hospitalization. A forerunner of this type of prevention was the implementation of the 'ouchless place model' in the 1990s (Schechter, 2008). The goals of this programme were to

provide a better integration of research into clinical practice and focused specifically on postoperative pain control, pain assessment, needle-related pain, and encouraging parental involvement in children's pain management. This type of model is essential to knowledge translation and the implementation of systematic programmes aimed at preventing and reducing acute pain in hospital.

Two important areas targeted by this model are procedural pain and postoperative pain. Because the timing and nature of these procedures are known in advance, it is possible to conduct longitudinal studies beginning prior to the procedures in order to identify risk and protective factors associated with the acute pain experience.

Systematic reviews of the literature on procedural pain have supported development of clinical practices guidelines that outline effective pharmacological and non-pharmacological interventions (including contextual, behavioural and cognitive strategies) to reduce procedural pain (e.g. Taddio et al., 2010) (see Table 5.3).

Research has also focused on reducing acute postoperative pain. One randomized controlled trial on the effectiveness of behavioural interventions on post-operative pain in children showed that behavioural preparation reduces anxiety before surgery and during induction of anaesthesia, and leads to lower frequency of emergence delirium, lower consumption of analgesic in the recovery room, and shorter stay in the recovery room (Kain et al., 2007). Guided imagery has also been found to reduce levels of pain and anxiety hours, but not 1 day after surgery when used 1 week and a few hours before surgery (Huth et al., 2004).

**Table 5.3** Evidence-based interventions to reduce procedural-related pain (i.e. immunization and injection pain) in infants, children, and adolescents

			Systematic reviews evaluating the effect of these interventions
Non-pharmacological management	Infants	Breastfeeding Kangaroo care (skin-to-skin contact) A sweet-testing solution Swaddling/facilitated tucking Rocking/holding Sucking-related interventions	(Pillai Riddell et al., 2011; Stevens et al., 2010)
	Children and adolescents	Psychological interventions: ♦ Distraction (e.g. music, cartoon movies) ♦ Relaxation breathing ♦ Information/preparation ♦ Combined cognitive-behavioural interventions Physical interventions/injection technique: ♦ Injecting the least painful brand during vaccination ♦ Having the child sit up ♦ Stroking the skin or applying pressure close to the injection site before and during injection; ♦ Injecting the most painful vaccine last when 2 vaccines are being administered sequentially during a single office visit; ♦ Performing a rapid intramuscular injection without aspiration.	(Cepeda et al., 2006; Chambers et al., 2009; Uman et al., 2006)
Pharmacological interventions		Topical anaesthetics (e.g. EMLA™)	(Taddio et al., 2009)

## Primary prevention of chronic pain

Very little is known about primary prevention of chronic pain mainly because most research is conducted when the pain is already present or chronic. One area that has received some empirical attention involves perioperative pain. Intervention strategies that aim to minimize acute postoperative pain intensity have the potential to play an important role in preventing the development of chronic post-operative pain. These interventions include pharmacological and psychosocial approaches to minimizing pain.

### Pre-emptive/preventive analgesia

Pre-emptive analgesia involves blocking pre- or intraoperative versus postoperative nociceptive inputs with the aim of preventing a state of central sensitization; thereby leading to less intense postoperative pain and lower analgesic consumption (Katz, 1995; Kissin, 2000). Preventive analgesia is a broader concept that aims to prevent the development of sensitization (peripheral and central) by blocking noxious inputs perioperatively (pre-, intra-, and postoperatively). Systematic reviews of the efficacy of pre-emptive analgesia are equivocal (Katz, 2003; Ong et al., 2005).

In contrast, more recent reviews suggest that preventive analgesia is more effective than the more narrow, classical view of pre-emptive analgesia in large part due to the blockade of nociceptive inputs across the perioperative phases of surgery (Katz and McCartney, 2002; Katz et al., 2011) and the use of more effective agents such as the alpha 2 delta ligands (Clarke et al., 2012). The focus of preventive analgesia is not on the relative timing of analgesic or anaesthetic interventions as is pre-emptive analgesia, but on attenuating the impact of the peripheral nociceptive barrage associated with

noxious preoperative, intraoperative, and/or postoperative stimuli. These stimuli induce peripheral and central sensitization, which increase postoperative pain intensity and analgesic requirements. Preventing sensitization reduces pain and analgesic requirements.

The reason why pre-emptive analgesic interventions have been equivocal is because the classic, two-group, pre- versus post-surgery design assumes that the intraoperative nociceptive barrage contributes to a greater extent to postoperative pain than does the post-operative nociceptive barrage. However, some studies have since shown that central sensitization is induced to an equal (or greater) extent by incision and intraoperative trauma, on the one hand (i.e. in the post-surgical treatment group), and postoperative inflammatory inputs and/or ectopic neural activity, on the other (i.e. in the preoperative treatment group), which would lead to non-significant intergroup differences in pain and analgesic consumption. The absence of significant differences in postoperative pain or analgesic consumption between the groups may point to the relative efficacy in reducing central sensitization of post incisional or postsurgical blockade, and not to the inefficacy of preoperative blockade (Katz et al., 2011).

The literature on paediatric pre-emptive/preventive analgesia (Yaster, 2010) is at best equivocal. Some studies have found that pre-emptive analgesia significantly reduces postoperative pain scores (Giannoni et al., 2001; Kundra et al., 1998) whereas similar studies fail to show a benefit (Giannoni et al., 2002; Ozcengiz et al., 2001).

### Psychosocial interventions

Researchers have examined the effectiveness of interventions aimed at reducing psychological distress and/or pain intensity during the

perioperative period. In a randomized controlled trial of cognitive behavioural therapy (information, coping skills training, combined information and coping skills training, or control group) administered once before and once after surgery, the combined intervention group showed reduced levels of pre- and post-surgical anxiety, whereas the coping skills group showed significantly reduced levels of postoperative anxiety and pain intensity (LaMontagne et al., 2003). As well, the control group exhibited the highest levels of postoperative pain 4 days after surgery compared to the treatment groups. Finally, the information-only group significantly increased their level of usual activities at 6 versus 3 months after surgery whereas younger children in the control or combined groups were more engaged in social activities compared to children in the coping group (LaMontagne et al., 2004). Similarly, a randomized controlled trial examining the effectiveness of behavioural interventions (family-centred behavioural preparation versus parental presence at induction versus oral midazolam versus control) found that children who received family-centred behavioural preparation before surgery exhibited lower preoperative anxiety, had a lower frequency of emergence delirium, consumed less analgesic in the recovery room, and were discharged faster from the recovery room compared to children in the other groups (Kain et al., 2007).

## Secondary and tertiary prevention of chronic pain

Psychological interventions including cognitive behavioural treatment, biofeedback, and/or relaxation can be effective in managing a wide array of pain problems, whereas pharmacological interventions appear to be more pain-condition specific. A Cochrane review has shown that psychological treatments are effective at reducing pain, but not disability, in children with headaches, fibromyalgia, and recurrent abdominal pain (Eccleston et al., 2009). A review of complementary and alternative medicine approaches has reported that children with recurrent headaches benefit significantly from hypnosis and guided imagery whereas other approaches, such as acupuncture, massage therapy, homeopathy, biofeedback, arts, and herbal therapy were found to be 'possibly efficacious' or 'promising' for other paediatric chronic pains (Tsao and Zeltzer, 2005).

One area of tertiary prevention that has received significant attention is headache. Chronic daily headaches and migraines are among the most frequent paediatric pain conditions. Reviews of pharmacological interventions show that acetaminophen, ibuprofen, and a sumatriptan nasal spray (Damen et al., 2005) as well as propranolol and flunarizine (Victor and Ryan, 2003) significantly reduce paediatric migraine-related symptoms. More high-quality randomized control trials are needed to establish the effect of additional drugs for which no trials of sufficient quality have been conducted (Damen et al., 2005; Victor and Ryan, 2003) in addition to examining the long-term potential of these drugs in preventing pain and related disability. Moreover, reviews have found that psychological therapies (Cvengros et al., 2007; Kroner-Herwig, 2011) are effective in treating paediatric headaches, but this effect was moderated by other variables, such as demographic and treatment characteristics.

Together, these results suggest that psychological and pharmacological factors play an important role in the secondary and tertiary prevention of chronic pain. More research is needed to examine the long-term benefits of using these interventions.

Recent adult chronic pain research indicates that the risk and protective factors involved in the transition to chronicity differ from those involved in the maintenance of already established chronic pain (Katz, 2012). For example, a prospective, longitudinal study of patients after lateral thoracotomy, showed that perioperative factors (i.e. preoperative pain disability, preoperative emotional numbing symptoms, and acute postoperative pain intensity) failed to predict the transition to chronic pain disability 6 months after surgery, but the very same variables measured 6 months later were highly significant predictors of the maintenance of 12-month chronic pain disability (Katz et al., 2009). Seebach et al. (2012) reported a similar pattern of findings in their prospective, longitudinal study of the psychosocial recovery trajectory in patients after spine surgery. The results indicate the risk factors that predict the maintenance of established chronic postsurgical pain disability or pain intensity, pain interference, and functional status are different from those that predict the initial transition to chronicity. Evidence for the distinction between triggering and maintaining factors in paediatric chronic post-surgical pain has been provided by Pagé et al. (2013) who showed that pain unpleasantness ratings 24 to 48 hours after surgery predicted the transition to moderate/severe CPSP at 6 months (but not 12 months), whereas 6-month anxiety sensitivity scores predicted the maintenance of moderate/severe CPSP (i.e. from 6 to 12 months after surgery). Implications of these findings for the design and conduct of paediatric studies and for pain prevention are discussed in the following section.

## Future research directions and clinical implications

The field of paediatric pain prevention, particularly chronic pain, is in its infancy. The search for risk and protective factors would be aided by well-designed, prospective, longitudinal epidemiological studies. These studies would: (1) assess participants prior to the onset of the procedure or as early as possible after injury or illness, (2) follow them until chronic pain has developed (i.e. 3–6 months), and (3) include a sufficient number of follow-ups to capture the critical window during which relevant processes and factors contribute to the transition to chronicity. It is crucial to assess outcomes at multiple time points because the transition to chronic pain and related psychosocial dysfunction is a dynamic process that evolves over time (Katz, 2012; Katz and Seltzer, 2009; Kehlet and Rathmell, 2010).

Such research would build on current observational studies of individual factors associated with the pain experience. This will lead to the development of integrative theoretical models of pain and disability adapted to paediatric populations, to a better understanding of the risk and protective factors involved in the transition of acute to chronic pain, and ultimately to clearer guidelines and recommendations for chronic pain prevention.

Current research on factors associated with the presence of chronic pain in children and mechanisms associated with the transition from acute to chronic pain can help further our understanding of the physical, pharmacological, and psychosocial correlates of paediatric chronic pain and provide important information for tertiary pain prevention. Prospective studies of the development of chronic pain and the transition from acute to chronic pain will help identify important risk factors, which can lead to the development of primary and secondary prevention strategies.

In addition, few randomized controlled trials have examined the effectiveness of psychological treatments in the treatment of paediatric chronic pain and disability and little is known about recent intervention strategies (e.g. acceptance and commitment therapy; Wickell et al., 2009) that successfully reduce pain-related disability. Systematic reviews show psychological treatment is effective for pain, but little evidence to support an effect on pain disability. Clinical trials are needed to extend the support of psychological treatment for pain to pain-related disability and other pain-related outcomes.

Many factors and mechanisms that affect the development and course of paediatric pain. Although there has been a growing body of literature over the last 15 years that explore the role of some factors influencing pain and pain-related disability, systematic reviews and meta-analyses are needed to identify the most important evidence-based factors and determine the specific and common factors associated with particular pain conditions. This will have enormous implications for the development of strategies to prevent unnecessary pain and suffering.

## CHAPTER 6

# Nociceptive signalling in the periphery and spinal cord

Suellen M. Walker and Mark L. Baccei

### Summary

Responses to painful or noxious stimuli are functional at birth. However, postnatal changes in the transmitters, receptors, and pathways involved in nociceptive signalling result in significant age-related changes in the nature and degree of response.

Noxious mechanical, thermal, and chemical stimuli are detected by peripheral nociceptors, transduced into electrical stimuli, and transmitted to the spinal cord. Within the spinal cord, there are significant postnatal changes in the balance of inhibitory and excitatory signalling, that not only influence the acute response to afferent input, but can also underlie long-term alterations in sensory processing following tissue injury in early life.

Evaluating age-related changes in nociceptive signalling is essential not only for understanding acute behavioural responses to noxious stimuli, but also for identifying the most appropriate and effective pain management interventions at different developmental ages.

### Introduction

Throughout postnatal development, there are significant functional and structural changes in the developing nervous system that influence nociceptive transmission. Patterns of innervation, receptor expression and distribution, and synaptic function within nociceptive pathways vary with age and influence the sensitivity and nature of response. This chapter describes the peripheral and spinal cord components of nociceptive processing, and outlines important age-related changes that influence the transmission and modulation of pain signalling in early life. Issues related to fetal nociception will not be discussed, as the marked differences between *in utero* and postnatal physiology also influence nociceptive signalling (Mellor et al., 2005).

The ability to detect and respond to potentially damaging environmental stimuli is an essential function that is maintained across species (Smith and Lewin, 2009). Infant rodents provide an established model for assessment of mammalian development and are frequently utilized to assess age-dependent changes in nociceptive mechanisms, with structural and functional methods that are not possible in clinical studies (Fitzgerald and Walker, 2009). The rat pup is born at a relatively immature stage, and data collected from human fetal tissue and rat pups suggest that the development of peripheral and spinal somatosensory function during the first postnatal week in the rat pup corresponds to preterm development

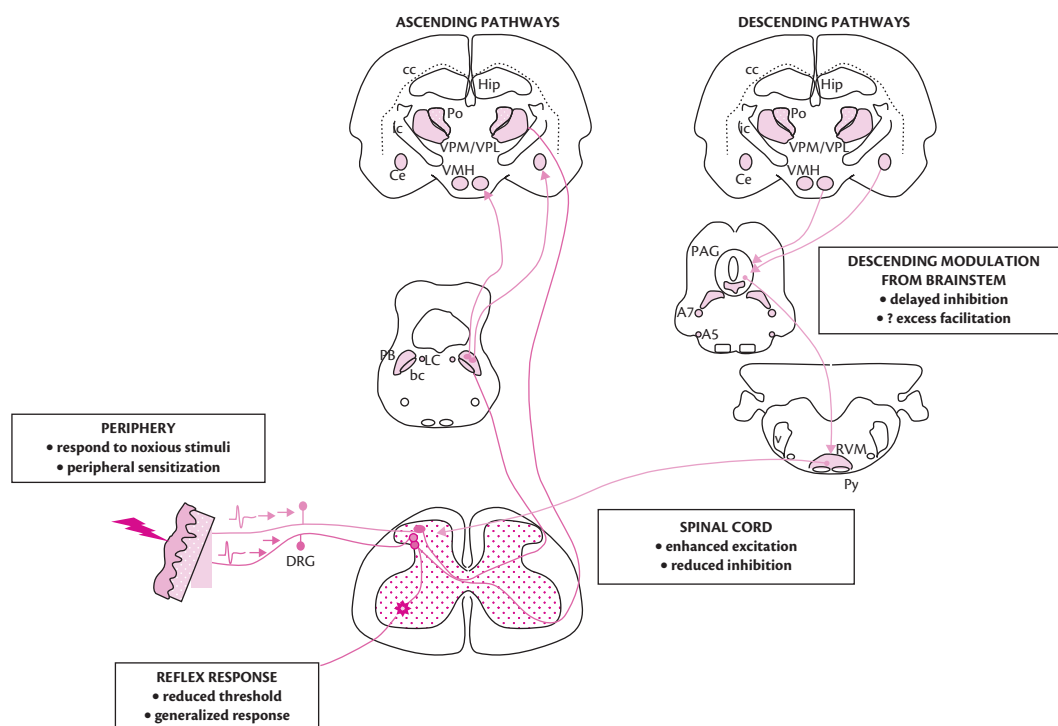

from 24 weeks until full-term birth at 40 post-conceptual weeks (Fitzgerald, 1991a). Pups mature relatively rapidly and can be considered infants by postnatal day (P) 7, and as children or young adolescents when they are weaned at P21. Rather than representing absolute correlations, these timelines provide a framework for assessing progressive changes in function throughout development, and it is important to note that different regions of the nervous system mature at different rates. Subsequent chapters will extend this discussion to: interactions between neurons and immune cells in nociceptive processing (Vega-Avelaira and Beggs, Chapter 7) and transmission to higher centres and modulation by brainstem centres (Fitzgerald, Chapter 8) (Figure 6.1). Visceral pain processing is discussed by Batra et al. (Chapter 27).

### Peripheral nociceptive pathways

‘Nociception’ refers to the physiological and pathophysiological component of sensory processing (which is the focus of the current chapter), whereas ‘pain’ encompasses sensory, emotional, and cognitive components. However, the terms are often used interchangeably, and will be for the purposes of this chapter.

One role of the peripheral nervous system is to sense and transduce potentially or actually damaging stimuli into electrical signals that are then transmitted along the axon to the central nervous system (CNS). Peripheral nociceptive pathways have four functional components (Woolf and Ma, 2007):

1. A nociceptor is a high-threshold sensory receptor of the peripheral somatosensory nervous system that is capable of transducing and encoding noxious stimuli. A stimulus is noxious if it is damaging or threatens damage to normal tissues (Merskey and Bogduk, 1994; see also updated IASP definitions <<http://www.iasp-pain.org/Content/NavigationMenu/GeneralResourceLinks/PainDefinitions/>>).
2. A peripheral branch of the axon that conducts the action potential and transports receptors/proteins from the cell body to the site of transduction. Two main groups of cutaneous afferents terminate as free nerve endings in the epidermis:
  - ♦ Myelinated A $\delta$  fibres associated with high-threshold, slowly adapting mechanoreceptors, and in addition a proportion respond to heat and cold.

**Figure 6.1** Diagrammatical representation of major nociceptive pathways. Textboxes highlight differences during early development.

- ♦ Unmyelinated C fibres, the majority of which are polymodal and respond to noxious mechanical, thermal and chemical stimuli. 'Silent' nociceptors become responsive to mechanical and/or heat stimuli after inflammation (Smith and Lewin, 2009).
- 3. The neuronal cell body in the dorsal root ganglion (DRG) is the major site for transcription and protein synthesis. In addition to sensory neurons, satellite glial cells are present in the DRG (see Vega-Avelaira and Beggs, Chapter 7, this volume, for further details). The small cell bodies of nociceptors are divided into two groups (Woolf and Ma, 2007):
  - ♦ Those that express tyrosine receptor kinase A (TrkA) and respond to nerve growth factor (NGF). These peptidergic nociceptors express calcitonin gene-related peptide (CGRP) and substance P (SP) and project to lamina I and lamina II outer in the superficial dorsal horn of the spinal cord.
  - ♦ Those that express Ret, the transmembrane signalling component of the receptor for glial cell-line derived neurotrophic factor (GDNF). These non-peptidergic neurons bind isolectin B4 (IB4), express the P2X<sub>3</sub> purine receptor, and project to lamina II inner in the dorsal horn (Hunt and Mantyh, 2001).
- 4. The central branch of the axon that projects from the DRG to the superficial dorsal horn and forms synaptic contacts with the second-order neuron. Presynaptic release of neurotransmitter (i.e. glutamate, substance P, brain-derived neurotrophic factor (BDNF)) is regulated by modulating calcium influx in the primary afferent terminal.

Peripheral nociceptive function has been evaluated by multiple experimental techniques, some of which have been conducted both in laboratory animals and in human experimental or clinical studies (Smith and Lewin, 2009). These include:

- ♦ Electrophysiology/microneurography recordings from sensory afferent fibres. This can be performed *in vitro* from isolated skin-nerve preparations (Koltzenburg et al., 1997; Reeh, 1986), or by *in vivo* studies in animals and humans (Koltzenburg and Handwerker, 1994).
- ♦ Analysis of receptor function and channel properties in cultured DRG neurons using patch clamp recordings and Ca<sup>2+</sup>-imaging techniques.
- ♦ Evaluating the organism's behaviour in response to noxious stimuli (e.g. changes in spinal reflex sensitivity).

An important protective function of the nervous system is its ability to detect and localize noxious stimuli and produce rapid reflex motor responses, which draw the affected area away from the potential injury. Evaluating spinal reflex sensitivity to peripheral stimuli allows quantification of the impact of both injury and/or analgesia (Le Bars et al., 2001; Walker et al., 2009). Although thresholds for eliciting reflex responses vary with age, correlations between stimulus intensity and reflex response have been demonstrated at all ages in laboratory animals (Holmberg and Schouenborg, 1996), and in human neonates (Andrews and Fitzgerald, 1999) and adults (Willer, 1983).

## Peripheral innervation

Nociceptive neurons are derived from neural crest cells in the dorsal part of the neural tube (Fitzgerald, 2005; Woolf and Ma, 2007). During embryonic development, sensory axons extend down the developing limbs to innervate the epidermis (Jackman and Fitzgerald, 2000). Larger-diameter A-fibre innervation occurs first, but by birth in the rat and by the second trimester in man, both A and C sensory fibres are distributed to all body regions (Fitzgerald, 2005). In rodent skin, fibres initially penetrate up to the epidermal

surface but then retract to form a subepidermal plexus that becomes more organized over the first 2 postnatal weeks and innervates end organs, such as sweat glands and hair follicles (Jackman and Fitzgerald, 2000). Navigation of sensory terminals to their target tissue is controlled by long- and short-range guidance cues that permit or inhibit axon growth (i.e. they are attractive or repulsive; Kolodkin and Tessier-Lavigne, 2011). Ephrins are a family of cell-surface signalling molecules involved in short-range axon guidance during development that includes class A ephrins interacting with multiple class A ephrin (Eph) receptors. Neural growth cones are inhibited by ephrin-A4, which is localized to the upper epidermis postnatally, thus restricting skin terminals to lower epidermal regions, and levels decrease as innervation stabilizes postnatally. However, levels of ephrin-A4 are also influenced by injury, and downregulation following neonatal full-thickness skin wounds contributes to persistent hyperinnervation (Moss et al., 2005; see Walker, Chapter 3, this volume for further details).

## Neurotrophins

In addition to established roles in modulating nociceptive sensitivity in adulthood (Pezet and McMahon, 2006), neurotrophins regulate multiple aspects of the development of sensory nerves (Fitzgerald, 2005), including:

- ◆ **Neuronal survival.** Neurotrophins promote the survival of specific types of neurons during development. NGF is present in the skin of the rat from birth (Constantinou et al., 1994), and is essential for nociceptor survival (Kirstein and Farinas, 2002). BDNF produced within sensory ganglia also plays a role in survival of nociceptive neurons responsive to NGF and GDNF (Valdes-Sanchez et al., 2010).
- ◆ **Innervation.** The pattern and density of skin innervation is regulated by access to local neurotrophic factors.
- ◆ **Nociceptor differentiation.** Levels of NGF and neurotrophin-3 (NT3) regulate the differentiation of A $\delta$  high-threshold mechanoreceptors and C-fibre nociceptors.
- ◆ **DRG neuronal phenotype.** During embryonic development, 70% to 80% of DRG neurons and almost all that project to the superficial dorsal horn express trkA and are NGF dependent. A subpopulation of neurons downregulate expression of trkA around the time of birth, and begin to express Ret, the signalling component for GDNF, leading to a postnatal increase in this IB4+ve population (Beland and Fitzgerald, 2001; Fitzgerald, 2005). Neurons that continue to express trkA remain as the peptidergic population and express CGRP and SP (Guo et al., 2001).

## Nociceptors and transduction

In adulthood, nociceptors have high thresholds for activation and respond to stimuli of sufficient intensity to cause damage. In addition, repeated stimuli can result in sensitization of the peripheral terminal, and release of neuropeptides from the terminal contributes to local vasodilation and erythema. DRG neurons respond to a range of peripheral mechanical, thermal, and chemical stimuli at birth (Fitzgerald, 1987b, 1987c). Age-related changes in receptor function and distribution, and in firing frequency, can alter sensitivity to different stimuli, but nociceptors are responsive to noxious stimuli and respond to tissue damage after birth (Fitzgerald and Walker, 2009).

## Thermal and chemical stimuli

Transient receptor potential (TRP) ion channels comprise a large family of receptors that transduce varying stimuli into electrical potentials (Wang and Woolf, 2005). Receptors expressed in sensory neurons or skin which respond in specific temperature ranges include TRPV1 to TRPV4, TRPM8, and TRPA1 (Patapoutian et al., 2009). Messenger RNA (mRNA) levels of the different receptors in the DRG, and neuronal responses to temperature and specific chemical ligands, change during postnatal development (Hjerling-Leffler et al., 2007).

- ◆ **TRPV1** is activated by temperatures greater than 43°C, but also by a range of chemicals including capsaicin, and its function is modulated by low pH. Changes in TRPV1 receptor expression and function, many of which are mediated by NGF, contribute to inflammatory hyperalgesia. Post-translational changes, which alter channel kinetics, and increased insertion of the receptor into the membrane, also contribute to increased sensitivity (Linley et al., 2010; Patapoutian et al., 2009). TRPV1 mRNA is present in the DRG prior to and after birth, and the receptors are functional as these neurons respond to capsaicin (Hjerling-Leffler et al., 2007). The delivery of TRPV1 to both peripheral and central terminals is developmentally regulated. TRPV1-positive nerve terminals are present in cutaneous structures at P10, but at a reduced density compared with adult animals (Guo et al., 2001) and the degree of sensitization to capsaicin by NGF is lower (Zhu et al., 2004).
- ◆ **TRPA1** is activated by noxious cold (<18°C in some but not all studies), and by pungent compounds such as horseradish, mustard, and formalin (Patapoutian et al., 2009). Responses to mustard oil have been recorded from DRG neurons in early development (Fitzgerald, 1987b, 1987c), but there is limited direct activation of spinal reflex responses in the first postnatal week (Fitzgerald and Gibson, 1984; Walker et al., 2007) when levels of TRPA1 mRNA are low in DRG neurons (Hjerling-Leffler et al., 2007) and central C-fibre connections are immature.
- ◆ **TRPM8** is activated by innocuous cold and cooling compounds such as menthol (Wang and Woolf, 2005). TRPM8 mRNA is present in DRG neurons at levels similar to the adult at P0, and although levels are reduced at P7 and P14, responses to menthol are present (Hjerling-Leffler et al., 2007).
- ◆ **Purinergic receptors** comprise a P2X family of ionotropic channels and a P2Y family of G-protein coupled receptors. The P2X<sub>3</sub> receptor and P2X<sub>2/3</sub> heteromultimers have the highest level of expression in sensory neurons. P2X<sub>3</sub> receptors on the sensory terminals of IB4+ve subpopulation of nociceptive neurons respond to adenosine triphosphate (ATP) that has been released from endothelial and Merkel cells and from sympathetic neurons. P2X<sub>7</sub> receptors also play an important role in inflammatory hyperalgesia (Burnstock, 2006). In early development, a higher proportion of DRG neurons express P2X<sub>3</sub> receptors, and this gradually becomes limited to IB4+ve neurons. In addition, P2X<sub>3</sub> agonists evoke a greater degree of depolarization and more marked behavioural response. There is also a reciprocal relationship with P2X<sub>7</sub> receptor expression on satellite glial cells, which increases as P2X<sub>3</sub> receptor expression decreases throughout postnatal development (Chen et al., 2012).

## Mechanical stimuli

Mechanoreceptors detect pressure stimuli at a range of intensities, and *in vivo* may be classified according to their threshold. A range of additional mechanical stimuli (e.g. light brush, texture, vibration, touch) can be detected via specialized nerve endings in skin and in association with specialized structures such as hair follicles, Meissner corpuscles, or Pacinian corpuscles (Delmas et al., 2011). Glabrous skin in the distal extremities (e.g. soles of feet/hindpaws) is more densely innervated than hairy skin, with a higher proportion of high threshold and faster conducting mechanosensitive fibres (Boada et al., 2010).

Low threshold mechanoreceptors (LTMs) respond to innocuous levels of pressure and are generally associated with A $\beta$  nerve endings. High-threshold mechanoreceptors (HTMs) are activated by noxious or injurious mechanical forces, and are associated with A $\delta$  and polymodal C fibres. Mechanosensitive neurons can also be differentiated by their firing frequency which encodes features of the mechanical stimulus (i.e. rapidly, intermediately, slowly, or ultra-slowly adapting), with nociceptive responses predominantly mediated by slowly and ultra-slowly adapting currents (Delmas et al., 2011). Transduction is thought to be the result of an ion channel that is opened directly by mechanical force, and candidate ion channels include acid-sensing ion channels (ASICs) and members of the TRP family (Woolf and Ma, 2007).

## Sodium channels

Voltage-gated sodium channels not only play an important role in transmission of the action potential along the axon, but different subtypes can modulate sensitivity, and are expressed along axons as well as in the peripheral intra-epidermal nerve endings (Dib-Hajj et al., 2010; Persson et al., 2010). Voltage-gated sodium channels (Na $_v$ ) may be either sensitive or resistant to tetrodotoxin (designated as TTX-S and TTX-R respectively). The TTX-S subtypes Na $_v$  1.3 and 1.7 and TTX-R subtypes Na $_v$  1.8 and 1.9 are expressed by nociceptors. Post-translational modifications enhance the excitability of TTX-R channels and contribute to peripheral nociceptor sensitization, and alterations in expression of Na $_v$  channels may occur in persistent pain states in adulthood (Lai et al., 2004; Liu and Wood, 2011).

Both TTX-S and TTX-R Na channels can be identified from birth in rat DRG (Ogata and Tatebayashi, 1992). Na $_v$  1.3 is expressed at higher levels during embryonic development. The TTX-R sodium channels Na $_v$  1.8 and Na $_v$  1.9 are expressed on C-fibres at birth and reach adult levels by P7 (Benn et al., 2001).

## Peripheral sensitization

The response to a given nociceptive stimulus can change with time, and sensitization of nociceptive pathways provides further warning and encourages protection of the injured part (Woolf and Ma, 2007). *Hyperalgesia* refers to an increased response to a noxious stimulus (increased response to suprathreshold stimuli) and *allodynia* refers to pain or nociceptor firing in response to a previously non-noxious stimulus (reduction in threshold and spontaneous activity). *Primary hyperalgesia* or peripheral sensitization is the result of altered nociceptor sensitivity, with an increased response to thermal and mechanical stimuli within the area of tissue damage. By contrast, *secondary hyperalgesia* refers

to increased sensitivity in the area surrounding the injured tissue, and is centrally-mediated.

Although initially advantageous, ongoing sensitization of nociceptive responses can become maladaptive and contribute to persistent pain states (Hucho and Levine, 2007; Woolf and Ma, 2007). It has recently been suggested that nociceptive pathways may be described not just as being in a naïve or a sensitized state, but that prior injury may induce a 'primed' state, in which the system is more responsive to future injury, such that lower concentrations of mediators can elicit enhanced and prolonged hyperalgesia (Hucho and Levine, 2007).

In early life, peripheral sensory fibres are also responsive to changing levels of activity in two different manners:

- ♦ Repeated stimuli can produce acute peripheral sensitization or hyperalgesia as seen at older ages (see later).
- ♦ Activity is required for strengthening synaptic connections and pathway development. During normal physiological development, activation of nociceptors is rare, and low threshold A-fibre input contributes to shaping of nociceptive circuits (Waldenstrom et al., 2003). Altering this balance of activity during critical periods in early life impairs normal development. Excessive *reductions* in afferent activity can alter synaptic function, structural and somatotopic organization in the spinal cord, and increase neuronal apoptosis resulting in long-term decreases in sensory thresholds (Beggs et al., 2002; Fitzgerald, 2005; Granmo et al., 2008; Walker et al., 2010). Excessive *increases* in activity as a result of pain and injury at specific developmental stages can also alter future sensitivity in a manner that is not seen following the same injury at older ages (Walker et al., 2009; for further details see Walker, Chapter 3, this volume).

## C-fibre stimuli

Sensitization of peripheral afferents following noxious or repeated stimuli can be demonstrated from early development, but the degree of activation by different stimuli can vary (Fitzgerald, 1987c, 1991b; Koltzenburg and Lewin, 1997). Mustard oil, which acts on TRPA1 receptors, produces only weak afferent responses in neonatal rat DRG recordings (Fitzgerald, 1987c), but does sensitize the nociceptor to subsequent stimuli within the area of injury, i.e. primary hyperalgesia (Fitzgerald, 1991b), although to a lesser degree than at older ages (P3 < P10 < P21; Walker et al., 2007). By contrast, secondary hyperalgesia, which is dependent on central mechanisms, is not induced by C-fibre stimuli (capsaicin or mustard oil) in the first postnatal week, but has reached adult levels by the third postnatal week (i.e. approximately late childhood; Jiang and Gebhart, 1998; Walker et al., 2007).

## Inflammation

Peripheral inflammation results in pain, heat, and redness (due to vasodilation), and swelling (due to plasma extravasation). An 'inflammatory soup' that is 'tasted' by receptors on nerve terminals (Woolf and Ma, 2007) is made up of multiple mediators including: prostaglandins (Kawabata, 2011), leukotrienes (Noguchi and Okubo, 2011), substance P, nitric oxide, cytokines, chemokines, bradykinin, serotonin, histamine, tumour necrosis factor (TNF $\alpha$ ) and neurotrophic factors (e.g. NGF). Following release from the nerve terminal, or from inflammatory cells or damaged tissue,

these mediators activate and/or sensitize the nociceptor terminal by acting on specific sensory receptors that include (Woolf and Ma, 2007; Linley et al., 2010):

- ◆ G protein-coupled receptors (e.g. bradykinin B1 and B2; protease-activated receptors, PAR 1–3; histamine receptors).
- ◆ Receptor tyrosine kinases (e.g. growth factor receptors such as trkA).
- ◆ Ionotropic receptors/ion channels, such as TRP channels (Patapoutian et al., 2009), purinergic receptors (Burnstock, 2006), and acid-sensitive channels.

Inflammatory mediators initiate intracellular signalling cascades, involving activation of a range of protein kinases (Bhave and Gereau, 2004; Hucho and Levine, 2007) and mediate increased sensitivity by:

- ◆ Rapid response post-translational changes which directly modulate ion channel activity, change membrane potential, or increase insertion of receptors into the membrane (Bhave and Gereau, 2004).
- ◆ Alterations in transcriptional programmes and changes in gene expression resulting in longer-term altered sensitivity (Linley et al., 2010), such as changes in the expression and transport of pro-nociceptive molecules (e.g. substance P, NGF) and ion channels.

Inflammatory hyperalgesia occurs from early development. Responses to thermal stimuli are enhanced following application of inflammatory mediators in skin-nerve preparations from embryonic chick (Koltzenburg and Lewin, 1997). Inflammatory stimuli, such as carrageenan and complete Freund's adjuvant (CFA), produce hyperalgesia in neonatal rat pups, and the degree and duration of response varies with the dose and type of agent (Ren et al., 2004; Walker et al., 2003). Hindpaw inflammation also accelerates the postnatal upregulation of IB4+ve neurons in the DRG (Beland and Fitzgerald, 2001). Although the pattern of response changes with age, hindpaw formalin injection also produces a significant behavioural response in rat pups (Guy and Abbott, 1992).

The acute and potential long-term effects of neonatal injury in different laboratory models are further discussed by Walker (Chapter 3, this volume).

## Nociceptive processing in the spinal cord

The processing of noxious information by the CNS begins in the superficial dorsal horn (SDH) of the spinal cord (laminae I–II), which receives direct projections from nociceptive primary afferent neurons (A $\delta$  and C fibres) with cell bodies in the DRG. The vast majority (>95%) of neurons within the SDH correspond to propriospinal and local circuit interneurons (Bice and Beal, 1997a, 1997b). As a result, the SDH network has the ability to integrate sensory inputs, which vary in modality, intensity, and location, and transform them into an output signal, which ascends to the brain. This output of the SDH circuit is conveyed by a small percentage of lamina I neurons (c.5%) which project to multiple supraspinal sites (Spike et al., 2003) and are known to be instrumental for the generation of chronic pain following tissue or nerve injury (Mantyh

et al., 1997; Suzuki et al., 2002). Importantly, the functional properties of the SDH network are highly age-dependent. As a result, understanding how the immature SDH is organized at a cellular and molecular level may yield new insight into novel approaches to regulate the ascending flow of noxious information to the brain, and resultant pain perception, in infants and children.

## Electrophysiological properties of neonatal dorsal horn neurons

Extracellular single-unit recordings in intact, anesthetized rodents clearly demonstrated that immature dorsal horn neurons are characterized by low thresholds, large peripheral receptive fields, and prolonged action potential after-discharges compared to adult dorsal horn cells (Fitzgerald, 1985; Torsney and Fitzgerald, 2002). Repetitive low-threshold stimulation also leads to a progressive sensitization of neonatal dorsal horn neurons, which disappears by P21 (Jennings and Fitzgerald, 1998). Notably, these same functional properties also characterize nociceptive withdrawal reflexes in the newborn rodent (Schouenborg, 2003), kitten (Ekholm, 1967), and human (Andrews and Fitzgerald, 1994; Andrews et al., 2002). The developmental alterations in the response of dorsal horn neurons following stimulation of their peripheral receptive fields may be explained by three factors:

- ◆ Developmental changes in sensory transduction and/or the functional properties of primary afferent neurons.
- ◆ Age-dependent changes in the intrinsic membrane properties of dorsal horn cells which influence the level of neuronal excitability.
- ◆ The maturation of excitatory and inhibitory synaptic inputs onto dorsal horn neurons. This section of the chapter will focus on the last two factors.

## Intrinsic excitability of developing SDH neurons

An important feature of developing CNS networks is spontaneous activity (SA), which can be generated by a variety of mechanisms (Blankenship and Feller, 2010) and contributes to both early circuit formation (Tritsch et al., 2007) and the subsequent establishment of appropriate sensory maps (Kandler et al., 2009). SA in the newborn SDH is predominantly localized to lamina I, and is then downregulated with age (J. Li and Baccei, 2011a). During early life, a subset of glutamatergic interneurons within lamina I function as 'pacemaker' neurons that are capable of generating oscillatory burst-firing. This is independent of synaptic transmission within the network and instead relies on a combination of intrinsic voltage-gated conductances (including persistent Na<sup>+</sup> currents and high-threshold N-type and L-type Ca<sup>2+</sup> channels). As these pacemaker neurons are innervated by nociceptive afferents and project throughout the dorsal–ventral axis of the immature spinal cord, they may provide an endogenous source of activity to the developing sensorimotor circuits mediating spinal nociceptive reflexes (J. Li and Baccei, 2011a). Alternatively, they may serve to synchronize the firing of ascending spinal projection neurons in the neonate. In this context, burst-firing also characterizes somatosensory processing in the developing human brain (Fabrizi et al., 2011).

The morphological and intrinsic membrane properties of SDH neurons appear to be developmentally regulated in a cell-type dependent manner.

- ◆ Supraspinal projection neurons undergo their axonal and dendritic development prior to birth (Bicknell and Beal, 1984), but ascending spinothalamic tract neurons increase in diameter during the first postnatal week (Davidson et al., 2010).
- ◆ Presumptive interneurons within the SDH exhibit extensive growth and reorganization of their dendritic trees during early life (Bicknell and Beal, 1984).
- ◆ The general population of laminae I and II neurons (mostly corresponding to interneurons) demonstrates an age-dependent hyperpolarization of the resting potential, decrease in membrane resistance and elevation in rheobase (amount of current needed to evoke an action potential), contributing to a decrease in excitability with maturation (J. Li and Baccei, 2011a; Walsh et al., 2009).
- ◆ Lamina I neurons projecting to the parabrachial nucleus and periaqueductal grey (PAG) differ from surrounding interneurons as their passive membrane properties and levels of spontaneous activity are stable during the first 3 weeks of life (J. Li and Baccei, 2012).

While the intrinsic firing properties of a neuron clearly depend on the expression of both voltage-gated and voltage-independent (i.e. 'leak') ionic conductances, surprisingly little is known about how age influences the expression of the underlying ion channels within developing spinal nociceptive circuits. Voltage-gated Na<sup>+</sup> currents are upregulated postnatally in the axonal (but not somatic) membrane of laminae I and II neurons (Safronov et al., 1999). This may occur in the absence of a significant shift in the Na<sup>+</sup> channel isoforms expressed within the region, as Na<sub>v</sub>1.2 and Na<sub>v</sub>1.3 are the dominant isoforms in rat laminae I and II neurons at both P6 to P9 and P25 to P30 (Hildebrand et al., 2011). In addition, these neurons demonstrate an age-dependent increase in the levels of fast, A-type voltage-gated K<sup>+</sup> currents, which may contribute to the observed rise in the prevalence of SDH neurons which exhibit delayed firing in response to intracellular current injection (Walsh et al., 2009). Meanwhile, although 'leak' currents (which can result from any ion channel open at the resting membrane potential) strongly modulate neuronal excitability in many areas of the CNS and can be regulated by a host of factors such as neurotransmitters, pH or anaesthetics (Goldstein et al., 2001), there are no data currently available regarding the molecular basis for these currents in developing SDH neurons.

Understanding how the expression of voltage-dependent and 'leak' channels in the SDH varies as a function of both age and specific cell type (i.e. GABAergic versus glutamatergic, interneuron versus projection neuron, etc.) could allow novel pharmacological strategies to target the output of spinal pain pathways in an age-specific manner.

## Maturation of primary afferent input to the developing SDH

Large myelinated A-fibre primary afferents penetrate the rat dorsal horn in a somatotopically appropriate manner at embryonic day (E) 15 (Mirnics and Koerber, 1995), and make functional

synaptic contacts in the SDH during early life (Coggeshall et al., 1996; Fitzgerald et al., 1994). Over the first 3 postnatal weeks, the majority of A fibres gradually retract to occupy deeper laminae in the dorsal horn, via activity-dependent mechanisms (Beggs et al., 2002). Some controversy exists regarding the extent to which these exuberant A-fibre terminals reflect low-threshold A $\beta$ -fibre inputs; at least some correspond to myelinated high-threshold mechanoreceptors (Woodbury and Koerber, 2003), and a proportion continue to project into lamina I-II throughout life (Boada and Woodbury, 2008). Regardless of whether A $\beta$  fibres make direct synaptic contacts onto laminae I and II neurons or communicate with these cells via polysynaptic pathways, significant evidence points to enhanced A $\beta$  input to the SDH during the early postnatal period:

- ◆ A $\beta$  fibre stimulation evokes the expression of c-fos (a marker of neuronal activation) in laminae I and II at P3 but not at P21 (Jennings and Fitzgerald, 1996).
- ◆ Patch clamp studies, which allow assessment of synaptic currents at a cellular level, have demonstrated an increased prevalence of polysynaptic A $\beta$ -input to neonatal GABAergic neurons within the SDH (Daniele and MacDermott, 2009).
- ◆ Repetitive stimulation of A $\beta$  fibres prior to P21 sensitizes neonatal dorsal horn neurons (Jennings and Fitzgerald, 1998).

As a result, less intense or low-threshold stimuli can elicit activation of neurons in the spinal cord in early life.

Small-diameter sensory afferents (A $\delta$  and C fibres) grow into the rat dorsal horn at E19 (Fitzgerald, 1987a) and likely have established a mature pattern of projections to the substantia gelatinosa (SG) by birth (Fitzgerald and Swett, 1983). However, the maturation of C-fibre synaptic connections within the developing dorsal horn is delayed:

- ◆ Electrical activation of high-threshold afferents fails to produce significant spike discharge in many newborn dorsal horn neurons (Fitzgerald, 1985, 1988).
- ◆ Chemical stimulation of C-fibres fails to evoke nociceptive withdrawal reflexes or neurogenic oedema until the second postnatal week (Fitzgerald and Gibson, 1984).
- ◆ Ultrastructural studies demonstrate increasing numbers of central terminals corresponding to fine-diameter primary afferents from P5 to P20 (Pignatelli et al., 1989).
- ◆ Capsaicin elevates glutamatergic signalling within the SDH to a greater extent at P10 compared to P0 (Baccei et al., 2003).

## Excitatory synapses in the developing SDH

All sensory neurons release glutamate from their central terminals in the spinal cord. Activation of ionotropic (AMPA, NMDA and kainate ion channel receptors) and/or metabotropic (mGluR, which signal via coupling with G-proteins), glutamate receptors results in membrane depolarization and increased excitability in dorsal horn neurons (H. J. Hu et al., 2007; P. Li et al., 1999; Yoshimura and Jessell, 1990). The functional properties of glutamate receptors depend on their subunit composition, and the relative expression of mGluR (Berthele et al., 1999; Valerio et al., 1997) and AMPAR subunits (Jakowec et al., 1995) within the dorsal horn vary according to postnatal age.

- ◆ GluR2 reduces the  $\text{Ca}^{2+}$ -permeability of AMPARs (Hollmann et al., 1991; Washburn et al., 1997). As neonatal rat SG neurons express a lower ratio of GluR2 to GluR1, 3, and 4 (Jakowec et al., 1995), AMPAR-dependent  $\text{Ca}^{2+}$  influx may be increased in neonatal spinal neurons, increasing excitability (Hartmann et al., 2004).
- ◆ NMDARs expressed by neonatal SDH neurons have a higher  $\text{Mg}^{2+}$  sensitivity and greater affinity for NMDA (Hori and Kanda, 1994; Green and Gibb, 2001). This suggests a distinct NMDAR composition during early life, but direct evidence is presently lacking.
- ◆ Synapses expressing only NMDARs (referred to as 'silent' synapses due to the block of the NMDAR by extracellular  $\text{Mg}^{2+}$  at resting membrane potentials) are present in laminae I and II at early postnatal ages (Baba et al., 2000; Bardoni et al., 1998; P. Li and Zhuo, 1998). 'Silent' synapses have been observed at high-threshold A $\delta$  fibre synapses onto NK1R-expressing lamina I neurons as late as P19 to P24 (Torsney, 2011). However, since 93% to 94% of glutamatergic synapses within laminae I and II of the neonatal rat express AMPAR subunits (Yasaka et al., 2009), the overall importance of 'silent' synapses for nociceptive processing within the developing SDH remains unclear.

## Synaptic inhibition within the developing SDH

### GABA and glycine

GABA and glycine serve as the major inhibitory neurotransmitters in the spinal dorsal horn via activation of two ligand-gated  $\text{Cl}^-$  channels (the GABA $_A$ R and glycine receptor), and are predominantly released from local interneurons, although descending inhibitory pathways from the brainstem may also include GABAergic and glycinergic projections (Kato et al., 2006). The number of GABAergic neurons within the rodent SDH peaks during the first two postnatal weeks (Dougherty et al., 2009; Ma et al., 1992; Schaffner et al., 1993) before declining to approximately 30% of the overall population during adulthood (Todd and Sullivan, 1990). Glycinergic neurons represent a subset of GABAergic neurons throughout embryonic and postnatal development (Berki et al., 1995; Huang et al., 2008; Todd and Sullivan, 1990). GABA and glycine are transported into the same synaptic vesicles by the vesicular inhibitory amino acid transporter (VIAAT) and co-released in the spinal cord, resulting in mixed GABA $_A$ -GlyR miniature inhibitory post-synaptic currents (IPSCs; Jonas et al., 1998).

GABAergic signalling dominates within lamina II of the neonatal spinal cord (Baccei and Fitzgerald, 2004). Glycinergic mIPSCs are absent in these cells during the first postnatal week, but these neurons respond robustly to exogenous glycine, suggesting that functional glycine receptors (GlyRs) are present but are not yet clustered at appropriate synaptic locations. This may reflect a reduced expression of gephyrin, a membrane protein known to interact with both GlyRs and the cytoskeleton in order to 'trap' the GlyR at synaptic sites in the membrane (Charrier et al., 2010; Kirsch et al., 1993).

From P8, mixed GABA $_A$ -GlyR mIPSCs are apparent in lamina I-II but are subsequently modulated in a regionally-specific manner. Within lamina I, the mixed responses are replaced by pure GlyR-mediated mIPSCs by P23, while in mature lamina II neurons

either GABA $_A$ -only or GlyR-only mIPSCs are observed. This shift results from an age-dependent reorganization of receptors in the postsynaptic membrane (Keller et al., 2001).

### Inhibition versus excitation

In mature neurons, the activity of the potassium-chloride ( $\text{K}^+$ - $\text{Cl}^-$ ) co-transporter KCC2 maintains low levels of intracellular  $\text{Cl}^-$ . Following activation of the GABA $_A$ R or GlyR and opening of the associated chloride channel,  $\text{Cl}^-$  flows into the cell, the membrane is hyperpolarized, and the neuron inhibited (Rivera et al., 1999). However, in many parts of the CNS, a low level of KCC2 during the neonatal period results in high levels of intracellular  $\text{Cl}^-$  and a reversal potential for  $\text{Cl}^-$  ions ( $E_{\text{Cl}}$ ) that is more positive than both the resting potential and action potential (AP) threshold (Ben-Ari, 2002). As a result, following GABA $_A$ R (or GlyR) activation,  $\text{Cl}^-$  moves out of the cell (down its concentration gradient), spike discharges can be evoked, and excitation (rather than inhibition) results in the developing network (Ben-Ari et al., 1989). Neonatal SDH neurons can depolarize in response to GABA $_A$ R activation (Baccei and Fitzgerald, 2004), and do not attain a mature  $\text{Cl}^-$  extrusion capacity until the third postnatal week (Cordero-Erausquin et al., 2005). This raises a critical question of whether GABAergic signalling within newborn spinal pain circuits is excitatory or inhibitory in nature.

Intrathecal administration of GABA $_A$ R antagonists (gabazine and bicuculline) at P3 significantly increased mechanical and thermal withdrawal thresholds, while the same antagonists at P21 decreased thresholds (Hathway et al., 2006). The GABA $_A$ R agonist midazolam sensitized nociceptive withdrawal reflexes in the neonate, but increased threshold at older ages (Koch et al., 2008). At first glance, these results appear to support the notion that GABA acts as an excitatory neurotransmitter within the newborn SDH. However, other evidence suggests that GABA has inhibitory actions in the SDH from birth. *In vitro* patch clamp studies demonstrated that  $E_{\text{Cl}}$  was consistently more negative than spike threshold even in neonatal SDH cells that depolarized in response to GABA, suggesting that GABA $_A$ R activation would ultimately limit action potential discharge and inhibit these neurons (Baccei and Fitzgerald, 2004). *In vivo* recordings from neonatal SDH neurons show that spinal application of gabazine enlarges receptive fields and enhances afferent-evoked discharge from the first days of life (Bremner et al., 2006) although spinal inhibitory circuits may be poorly tuned in the neonate (Bremner and Fitzgerald, 2008). Collectively, these results suggest that GABAergic synaptic inhibition in the SDH is functional from birth.

This apparent discrepancy can be explained if the excitatory actions of GABA on reflex sensitivity are not the direct result of its actions in the dorsal horn, but also involve modulation by supraspinal activity. Following transection of the neonatal spinal cord, intrathecal GABA $_A$ R antagonists facilitate nociceptive withdrawal reflexes in a similar manner as at P21, and gabazine also enhances primary afferent-evoked ventral root potentials in the isolated neonatal spinal cord (Hathway et al., 2006). This supports a role for supraspinal structures in modulation of neonatal cutaneous reflex sensitivity. While reflex behaviour undoubtedly provides insight into how the nervous system processes noxious information, measuring only the motor output of the spinal cord network may not specifically indicate the level of excitability within the ascending sensory pathways that project to the cortex.

## Signal processing in the developing SDH under pathological conditions

Understanding pain mechanisms in early life requires additional knowledge of how tissue and nerve damage modulate both the intrinsic membrane properties of immature dorsal horn neurons as well as their synaptic inputs.

Peripheral inflammation significantly increases spontaneous firing and receptive field size in neonatal dorsal horn neurons within hours after the injury (Ririe et al., 2008; Torsney and Fitzgerald, 2002), which at least in part results from an injury-evoked enhancement in the intrinsic excitability of immature dorsal horn cells (Rivera-Arconada and Lopez-Garcia, 2010). However, inflammation may evoke biphasic changes in the membrane properties of developing SDH neurons, as this short-term enhancement in intrinsic excitability is followed (at c.20 hours post-injury) by an upregulation of sustained voltage-gated K<sup>+</sup> currents and *reduction* in excitability (Rivera-Arconada and Lopez-Garcia, 2010). Meanwhile, neonatal sciatic nerve injury failed to alter neuronal excitability in the SDH, although it did unmask increased sensitivity to the pro-inflammatory cytokine TNF $\alpha$  (J. Li et al., 2009b).

The effects of peripheral tissue and nerve damage on synaptic function within spinal nociceptive networks are highly age-dependent. Tissue damage during early postnatal development evokes an activity-dependent elevation in glutamate release within the SDH (J. Li and Baccei, 2009; J. Li et al., 2009a). Synaptic inhibition was not significantly affected (J. Li and Baccei, 2009), which is in contrast to the adult dorsal horn where a reduction in the efficacy of glycinergic inhibition is thought to make a key contribution to inflammatory hyperalgesia (Harvey et al., 2004; Hosl et al., 2006; Muller et al., 2003). Similarly, while peripheral nerve injury compromises GABAergic inhibition in the adult (Moore et al., 2002; Scholz et al., 2005), it had no significant effects on synaptic transmission within lamina II in the neonate (J. Li et al., 2009b). However, it remains possible that injury-evoked changes in the expression of KCC2 (and thus Cl<sup>-</sup> homeostasis) occur within the neonatal SDH, as reported previously in the adult (Coull et al., 2003; Zhang et al., 2008), which could reduce the functional strength of synaptic inhibition within immature spinal nociceptive circuits.

Injury-induced facilitation of excitatory signalling is also associated with an increased efficacy of nociceptive synapses within the immature SDH. Surgical incision selectively enhanced glutamatergic responses mediated by high-threshold (i.e. A $\delta$ - and C-fibre) primary afferent neurons in a manner consistent with an elevated number of nociceptive synapses in the region (J. Li and Baccei, 2011b). Sensory neurons expressing TRPV1 contribute to this nociceptive synaptic plasticity, as selective destruction of these fibres by prior systemic capsaicin prevented the injury-evoked increase in spontaneous glutamate release (J. Li and Baccei, 2011b). In addition, peripheral inflammation in the neonate, but not adult, leads to a proliferation of nociceptive primary afferent projections to the SDH (Ruda et al., 2000; Walker et al., 2003). While the mechanisms underlying this strengthening of nociceptive synaptic input are not fully understood, NGF signalling at the trkA receptor is likely to play a role (J. Li and Baccei, 2011b).

## Persistent effects of early tissue injury on SDH network function

Tissue damage during a critical period of early life can evoke long-term changes in pain sensitivity in rodents, with many studies reporting a baseline hypoalgesia accompanied by an exaggerated hyperalgesia following re-injury during adulthood (see Walker, Chapter 3, this volume). These prolonged changes in nociceptive processing could, in part, reflect long-term alterations in the function of spinal pain circuits, as brief inflammation of the neonatal hindpaw is known to result in significant changes in gene expression within the adult dorsal horn (Ren et al., 2005). However, the extent to which early tissue damage modulates intrinsic membrane properties and synaptic function within the mature SDH network remains unclear.

The majority of behavioural studies have identified the first postnatal week as the 'critical period' during which tissue damage is capable of altering pain sensitivity throughout life (LaPrairie and Murphy, 2007; Ren et al., 2004; Walker et al., 2009). This correlates well with the ages at which tissue damage elevates glutamatergic signalling within the SDH (J. Li and Baccei, 2009; J. Li et al., 2009a). Nonetheless, the mechanistic basis for the critical period within the developing SDH currently remains unknown. One possibility is that the gradual maturation of inhibitory synaptic transmission within the SDH (Baccei and Fitzgerald, 2004; Cordero-Erausquin et al., 2005; Ingram et al., 2008; Keller et al., 2001) is involved in terminating the critical period (Hensch, 2004). Closure of the critical period also coincides with the onset of myelination in the spinal cord (Kapfhammer and Schwab, 1994). CNS myelin contains proteins that potently inhibit axonal growth (F. Hu and Strittmatter, 2004), and enhanced collateral sprouting of nociceptive fibres has been observed in the mature dorsal horn in the presence of reduced myelination (Schwegler et al., 1995); and experience-dependent plasticity in the visual cortex persists throughout life in mice lacking normal myelin-derived signalling at the Nogo receptor (McGee et al., 2005). Future identification of factors responsible for closing the critical period for plasticity within developing spinal pain circuits may identify potential strategies to limit the long-term effects of neonatal tissue damage.

## Conclusions and clinical implications

Nociceptive signalling in the periphery and spinal cord in early life has the following features:

- ◆ Peripheral nociceptors are functional and respond to a range of chemical, thermal and mechanical stimuli.
- ◆ Prolonged noxious stimuli or inflammation produce peripheral sensitization.
- ◆ The structure and function of spinal cord nociceptive pathways continues to mature across the first 2 to 3 postnatal weeks in the rodent, a period which may extend throughout infancy and early childhood in humans.
- ◆ Spinal cord signalling is initially characterized by an excess of excitatory effects and delayed development of inhibitory mechanisms.
- ◆ Spinal reflex responses have low thresholds and are poorly localized in early life.

Clinical studies evaluating peripheral nociceptive function in neonates and infants show parallels with the patterns of reflex response and changes in sensitivity described. Spinal reflex thresholds are lower in neonates and infants, but a clear relationship between the degree of response and intensity of the stimulus is maintained (Andrews and Fitzgerald, 1999). Sensitization of reflex responses has clearly been demonstrated following repeated mechanical stimuli (Andrews and Fitzgerald, 1994), repeated heel lance for blood tests (Fitzgerald et al., 1988), and surgery (Andrews and Fitzgerald, 2002) in neonates and infants.

An early study evaluating the response of neonates to skin scratch allergy tests demonstrated histamine-induced erythema even in preterm neonates (Matheson et al., 1952), and along with clinical observations following surgery, suggests that localized inflammatory responses are functional in early life.

Clinical investigations of genetic disorders also demonstrate the importance of nociceptive mechanisms throughout early life. Mutations affecting genes encoding the trkA receptor for NGF can result in congenital insensitivity to pain and anhidrosis (Indo, 2002). Loss-of-function mutations affecting Na<sub>v</sub> 1.7 channels on nociceptive afferents result in congenital insensitivity to pain, while gain of function mutations produce episodic severe pain syndromes (paroxysmal extreme pain disorder or erythromelalgia) that may present in infancy or childhood (Fischer and Waxman, 2010; see also Walker, Chapter 21, this volume).

Integration of data from laboratory studies is essential to improve our understanding of the changing impact of pain and injury throughout development, interpret clinical observations, and ultimately improve the management of pain for neonates, infants, and children of all ages.

## CHAPTER 7

---

# Neuroimmune interactions and pain during postnatal development

David Vega-Avelaira and Simon Beggs

### Summary

The immune system is essential for identifying and mounting defensive responses to tissue damage and infection. In addition, it is increasingly recognized that interactions between immune cells and nociceptive pathways can modulate pain sensitivity. The role and function of immune cells in the central nervous system changes during postnatal development, and as a result, the impact of neuroimmune interactions on pain signalling varies with both age and the type of injury.

### Introduction

Interactions between nociceptive pathways and the immune system are important for detecting and responding to potential harm from tissue damage and infection, and involve multiple different cell types in different regions (Figure 7.1). In the periphery, nociceptors release a range of mediators which not only contribute to peripheral sensitization, but also attract and activate immune cells (mast cells, dendritic cells, T lymphocytes) to facilitate removal of pathogens and wound healing (Chiu et al., 2012). Macrophages are T lymphocytes which are present in the dorsal root ganglion (DRG), and increased activity and recruitment following nerve injury can contribute to pain sensitivity (Hu et al., 2007). In the spinal cord, microglia are no longer thought of as having only immune surveillance and supportive roles. Following noxious afferent input, microglial reactivity is increased, and the released proinflammatory cytokines, chemokines, and extracellular proteases, interact with neurons and contribute to central sensitization (Beggs and Salter, 2010; Clark et al., 2011). Astrocytes, another subtype of glial cells, are also activated in the spinal cord following inflammation, plantar incision, and nerve injury, but the degree and time course differ from microglia, and varies with the type of injury (Chiang et al., 2012). Modulators of glial activity reduce pain sensitivity associated with injury, but have little effect on normal or baseline pain processing, suggesting that the main role of glial activation is in pathological pain states (Chiang et al., 2012).

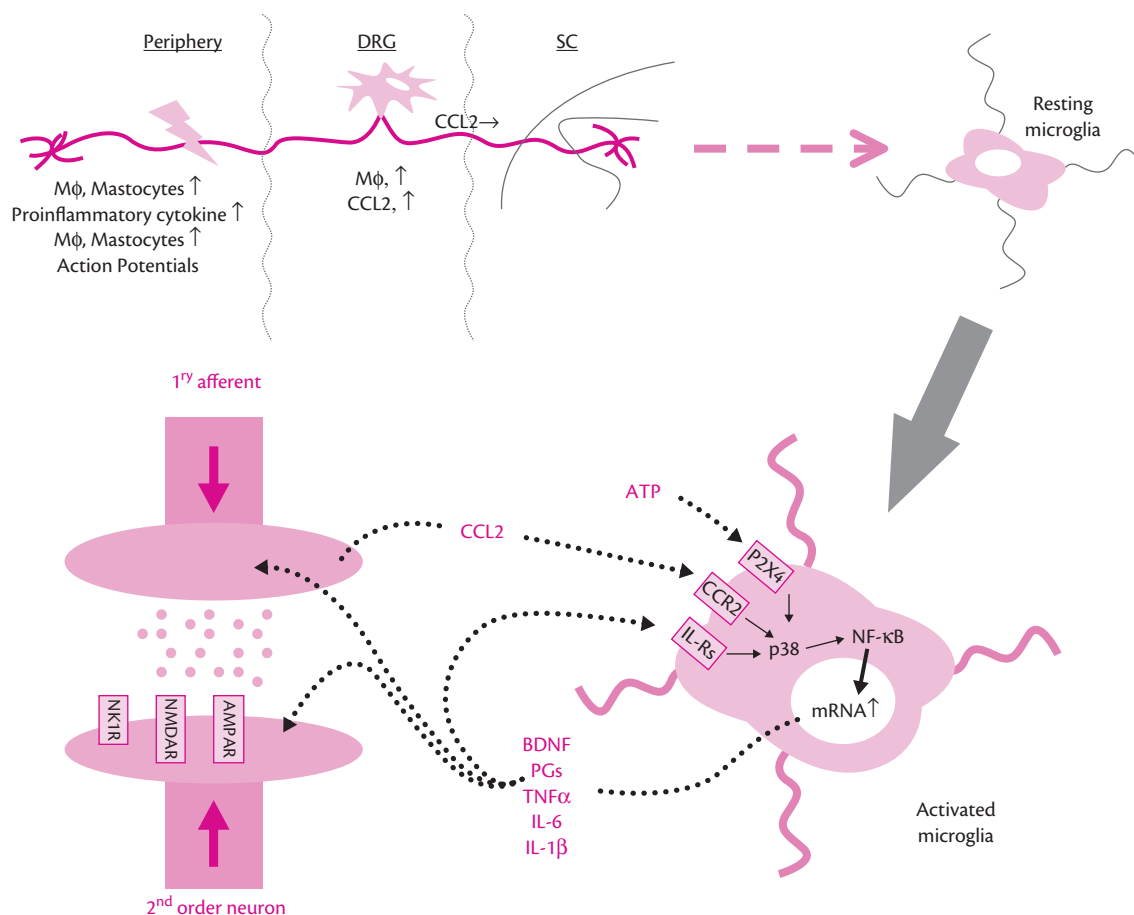

### Peripheral nerve injury

Neuropathic pain can be severe and difficult to treat (see also Walker, Chapter 21; Rastogi and Campbell, Chapter 49, this volume). Despite considerable effort the conditions that initiate and maintain neuropathic pain are as yet not fully understood. Peripheral nerve injury (PNI) activates multiple cellular and molecular pathways in both the peripheral and central nervous systems. Of considerable interest now is parsing these cellular and molecular pathways; PNI will evoke a nerve regeneration response and a stress response associated with interrupted metabolic pathways (Costigan et al., 2009). Clearly, explicit damage to the peripheral nervous system is countered by responses in multiple systems, and it is the interaction between immune system reactivity and injury-driven changes in nociceptive signalling that is now under scrutiny.

PNI in experimental animals under 3 weeks of age does not result in the development of pain hypersensitivity, although evidence suggests that the onset is delayed (Howard et al., 2005; Vega-Avelaira et al., 2012). This developmental anomaly is due, at least in part, to differences between the early postnatal and adult immune systems (Moss et al., 2007; Vega-Avelaira et al., 2007, 2009).

### Microglia

Microglia are the resident macrophages of the central nervous system (CNS). Their complex repertoire of functions in the adult includes maintaining homeostasis, detecting and responding to infection, and promoting or suppressing neuroinflammation. These actions also link microglia inextricably to neurodegenerative diseases such as Alzheimer's disease, Parkinsonism, and neuropathic pain (Beggs et al., 2012b; Kettenmann et al., 2011). Microglia respond to potentially damaging injury or disease to the CNS by adopting any of several reactive phenotypes. Morphological changes can be identified by changes in expression of the microglial marker, ionized calcium binding adaptor molecule1 (Iba-1; Beggs and Salter, 2007; Suter et al., 2009; Vega-Avelaira et al., 2007). Where once the concept of a monolithic microglial 'activation' was widely accepted, evidence now suggests there are different subpopulations

**Figure 7.1** Neuroimmune interactions in neuropathic pain. Peripheral nerve injury provokes activation of innate immune cells such as macrophages and mastocytes proximal to the damaged area (Hu and McLachlan, 2002, 2003; Watkins and Maier, 2002). As a consequence, both immune cells and Schwann cells secrete pro-inflammatory cytokines to prevent further injury and repair the damage. This promotes physiological, cellular, and molecular changes in the DRG neurons and macrophages which result in neuronal aberrant electrical discharges, macrophage activation and pro-inflammatory cytokine release (Gabay et al., 2011; Hu and McLachlan, 2002; Ozaktay et al., 2006; Suter et al., 2009). Cytokines, such as CCL2 are anterogradely transported from the ganglia to the primary afferents terminals in the spinal cord (Thacker et al., 2009). Acting through CCR2 and interleukin receptors they activate intracellular pathways (e.g. P38 map kinase pathway), promote translocation of transcription factors like NF- $\kappa$ B to microglia nuclei, and become activated (Capiralla et al., 2012; Chang and Waxman, 2010; Ren and Dubner, 2007; Schäfers et al., 2003; Svensson et al., 2003). As part of the activation process, microglia produce and release cytokines with an autocrine and paracrine activity which create a feedback positive loop that will sensitize second-order neurons and initiate the neuropathy (X. Gao et al., 2005; Y.-J. Gao and Ji, 2009, 2010).

with different reactive response profiles and capabilities (Scheffell et al., 2012).

Microglia are sensors for damage or disease in the CNS, capable of detecting pathogen-associated molecular patterns (PAMPs) and damage-associated molecular patterns (DAMPs). One of the many classes of receptors expressed by microglia are the Toll-like receptors (TLRs). TLRs are part of the complex molecular sensor framework for detecting both PAMPs and DAMPs (Stewart et al., 2010; Zhang and Mosser, 2008) and members of this family of receptors have been implicated in the pathogenesis of neuropathic and inflammatory pain in adult animals (Sorge et al., 2011; Tanga et al., 2005).

### Microglial function during development

Microglia are of haematopoietic origin, and first appear as primitive macrophages in the yolk sac in early embryogenesis from where they migrate into the CNS (Ginhoux et al., 2010). This process occurs throughout embryonic and into early postnatal life (Pont-Lezica et al., 2011). The actions of microglia during

development are complex with a dual function as: (1) immune effectors in the removal of excess and exuberant axonal projections, and (2) a more classical glial role as cytotoxic and cytotrophic factors (Schlegelmilch et al., 2011). Given the extensive remodelling and refining of connectivity throughout the CNS in the early postnatal period, it is clearly necessary for microglia to differentiate between normal physiology and pathology.

The induction of cytokines and chemokines resulting from TLR4 activation varies with postnatal age and the pattern is the same across the TLR family members, with a general *hyporesponsivity* that peaks at postnatal day (P) 21. The transient changes and hyporesponsivity of some TLRs may be a reflection of the substantial reorganization and refinement of connectivity within the dorsal horn (and CNS generally) that occurs postnatally. Normal developmental synaptic elimination and pruning of exuberant axonal projections would provide a temporary increase in DAMPs and provoke an unwanted immune response.

This time point marks the end of a critical period of maturation of both the nervous and immune systems, and also the point

at which central neuroimmune interactions stimulated by PNI are capable of driving neuropathic behavioural pain behaviours (Howard et al., 2005; Moss et al., 2007). Intriguingly, this postnatal maturation is also marked by a switch in gene expression such that gene transcripts associated with the classical, pro-inflammatory M1 phenotype are downregulated while those of the alternative anti-inflammatory M2 phenotype start to predominate (Gordon and Taylor, 2005; Mosser and Edwards, 2008; Scheffell et al., 2012).

## T lymphocytes

T cells, also known as T lymphocytes, play an important role in cell-mediated immunity, but there is also increasing evidence for a role of T cells in the responses to PNI that produce pain. Helper T cells can be divided into two broad subtypes; Th1 and Th2, classified as such by the array of cytokines they produce. Th1 is generally pro-inflammatory and released cytokines include interferon gamma (IFN $\gamma$ ), which is heavily implicated in neuropathic pain pathogenesis (Costigan et al., 2009; Masuda et al., 2012; Tsuda et al., 2009). Th2 is generally anti-inflammatory, and ideally a balance of Th1 and Th2 exists. In early life, the Th1 pro-inflammatory response is weak (Fadel and Sarzotti, 2000), and the balance is shifted to a Th2 predominance, with Th1 gradually strengthening with exposure to allergens.

The complex developmental regulation of the immune system is occurring at the same time as the nervous system is undergoing extensive postnatal refinement (Beggs et al., 2002; Fitzgerald, 2005; Fitzgerald et al., 1994), it is not surprising that interactions of the immune system with the CNS following PNI differ significantly in the early postnatal period from those seen in the adult. Taken together, these observations indicate that the immune system in the immediate postnatal period does not react to PNI in the same way as in the mature adult animal. The pattern of T-cell activation and infiltration following PNI differs significantly in young animals. The predominance of Th2 T cells in the neonate underlies this, imbuing the immature immune system with a tolerance for the new antigens exposed by normal developmental changes within the CNS (Costigan et al., 2009).

## Neuroimmune interactions in dorsal root ganglia

Macrophages are phagocytic immune cells, capable of engulfing and digesting cellular debris and pathogens, and act to maintain the cellular environment and protect against potential infection in the DRG (Watkins and Maier, 2002). In keeping with resident microglia in the CNS, macrophages in the DRG adopt a ramified surveillance state and are homogeneously distributed between neuronal cell bodies and projecting fibres (Beggs et al., 2012b; Hu and McLachlan, 2002, 2003; Vega-Avelaira et al., 2009). PNI provokes both a reactive response of the resident macrophages as well as infiltration of new macrophages from the circulation (Hu and McLachlan, 2002, 2003). Macrophages in the DRG are characterized by expression of the 'macrophage scavenger receptor' CD163, and can also be identified by expression of CD68, which is increased 3 days following experimental PNI in adult animals (Hu et al., 2007). CD168-positive cell number remains the same, suggesting a reactive phenotypic switch in the normal resident macrophage population. Macrophage reactivity peaks at 7 days post injury, as shown by the adoption of

an amoeboid morphology and maximal proliferation, and persists for at least 3 months (Hu and McLachlan, 2002). Retrograde labelling studies have shown that these reactive macrophages cluster around damaged neurons and in particular the large cell bodies of myelinated afferents (Vega-Avelaira et al., 2009).

The injury-induced reactive phenotype of DRG macrophages is determined in part by their molecular phenotype. Increased expression of membrane receptors such as purinergic receptors (e.g. P2X<sub>4</sub>) and chemokine receptors (e.g. IL6R, TNF $\alpha$ R, CCR2) activate intracellular second-messenger pathways (e.g. MAP kinases pathway; Gao and Ji, 2010; Ji et al., 2003, 2009; Scholz and Woolf, 2007), leading to increased expression of molecules that drive a phagocytic phenotype. This is accompanied by the release of chemokines (Hu and McLachlan, 2003) which maintain this adaptive phenotype through both autocrine and paracrine positive feedback loops and by macrophage recruitment from the circulation. Chemokines also act directly to influence neuronal excitability (Scholz and Woolf, 2007), thereby modulating afferent signal transduction from the dorsal root ganglia to the spinal cord.

## Signalling molecules

### MCP-1/CCL2

Macrophage chemo-attractant protein 1 (MCP-1, now CCL2) and its receptor CCR2 have been associated with several models of nerve injury (Thacker et al., 2009; Vega-Avelaira et al., 2009). MCP-1 is expressed in small DRG neurons and is transported anterogradely to the spinal cord after PNI where it has chemotactic effects on both glia and neurons (Thacker et al., 2009) (Figure 7.1). Genetically modified CCR2 null or 'knock-out' mice do not exhibit enhanced pain behaviour after PNI (Abbadie et al., 2003; Zhang et al., 2007). Taken together, these studies directly implicate macrophage-neuronal interactions in pain behaviour.

### Tumour necrosis factor $\alpha$ (TNF $\alpha$ )

TNF $\alpha$  is a pro-inflammatory cytokine and one of many factors released following PNI (Jeon et al., 2011; Kim et al., 2011). Macrophages are the main source of TNF $\alpha$  but *de novo* expression is also evident in small-diameter nociceptive cells after nerve injury. TNF $\alpha$  activates the MAP kinase p38 intracellular pathway which instigates a feed-forward mechanism to increase further production of TNF $\alpha$ . Pharmacological blockade of TNF $\alpha$  is sufficient to ameliorate pain behaviour in animals with partial axotomy (Schäfers et al., 2003).

### Interleukin-6 (IL-6)

IL-6 is a pleiotropic cytokine (Simpson et al., 1997) with roles in neuronal survival, growth and differentiation (Grothe et al., 2000). It is synthesized and released by macrophages and Schwann cells. The IL-6 receptor (IL-6R or CD126) is expressed in the DRG (Brázda et al., 2009; Watkins and Maier, 2002; Zhang et al., 2007) and there is evidence for IL-6 involvement in both the hyperalgesia and allodynia associated with neuropathic pain (DeLeo et al., 1996). IL-6 production is increased in neurons and satellite glial cells in DRGs within 24 h of PNI and persists for at least 2 weeks (Brázda et al., 2009). Furthermore, IL-6 has roles in multiple independent pathways mediating processes including nerve regeneration (Qiu et al., 2005) and TNF $\alpha$ -induced

apoptosis of DRG neurons (Murata et al., 2011). As contradictory evidence exists for both beneficial and detrimental effects of IL-6 after PNI, further investigation is warranted.

### Interleukin-1 $\beta$ (IL-1 $\beta$ )

IL-1 $\beta$  is intimately associated with the initiation and maintenance of neuropathic pain (Gabay et al., 2011; Wolf et al., 2006). It is constitutively expressed in primary sensory neurons (Coprav et al., 2001) and has pro-excitatory effects in small and medium non-peptidergic neurons (Stemkowski and Smith, 2012) via a G protein-coupled receptor mediated mechanism (von Banchet et al., 2011). PNI induces a rapid increase in IL-1 $\beta$  in DRG macrophages (Thacker et al., 2007), sensitizing DRG neurons and contributing to increased mechanosensitivity (Ozaktay et al., 2006).

### Prostaglandins

Prostaglandins, such as cyclo-oxygenase (COX)-2 dependent PGE<sub>2</sub>, have an important role in the pathogenesis of neuropathic pain (Ma and Quirion, 2008; Ma et al., 2010). At the spinal cord level, COX-2 is upregulated within the first 3 days after injury (O'Rielly and Loomis, 2006), and in the periphery, COX-2 and PGE<sub>2</sub> production is upregulated in Schwann cells and macrophages infiltrating damaged nerves. PGE<sub>2</sub> receptors, such as EP<sub>1</sub> receptors, are expressed on DRG neurons, and nerve injury causes the upregulation of EP<sub>1</sub> in human and rat DRG neurons (Durrenberger et al., 2006; Ma et al., 2010). PGE<sub>2</sub> sensitizes damaged axons to mechanical and heat stimuli (Ma and Quirion, 2008; Michaelis et al., 1998), and increases production of substance P and calcitonin gene-related peptide in DRG neurons (Segond von Banchet et al., 2003).

### Nitric oxide (NO)

Macrophages are a main source of nitric oxide (NO) after nerve injury (Moalem and Tracey, 2006), induced by TNF $\alpha$  via inducible NO synthase (iNOS) (Lowenstein et al., 1994). NO upregulates prostaglandin production and contributes to neuronal sensitization (Mollace et al., 1997; Purwata, 2011).

## Nerve injury and spinal microglial reactivity

Increased microglial reactivity has been demonstrated in several animal models of PNI associated with chronic pain (Coull et al., 2005; Tsuda et al., 2003; Vega-Avelaira et al., 2009; Zhuang et al., 2005). Initiation of the microglial response after peripheral nerve damage is triggered by increased neural activity of sensory afferent fibres (Suter et al., 2009). Nociceptive stimuli are predominantly transmitted by A $\delta$ - and C-fibres (see Walker and Bacceti, Chapter 6, this volume). However, following nerve injury, activity in A $\beta$ -fibres which normally transduce innocuous tactile sensation can contribute to persistent pain (Matsumoto et al., 2008). Afferent blockade with the local anaesthetic bupivacaine, which blocks conduction in all sensory neurons (C, A $\delta$ , and A $\beta$  fibres) prevented nerve injury-induced spinal microglial activation; but resiniferatoxin, which selectively blocks peripheral input from C and A $\delta$  nociceptive fibres (Mitchell et al., 2010) had no effect (Suter et al., 2009). This suggests that the large myelinated fibres have an important role in the switch of microglia to a reactive phenotype after nerve injury. It has also been suggested that a small proportion of microglia are activity-independent, responding to retrograde axonal transport

and cytokine stimulation (Abe and Cavalli, 2008; O'Brien and Nathanson, 2007). Microglia also respond to chemotactic factors and migrate towards the area in the spinal cord that receives the projections of degenerating C-fibre primary afferents (Beggs and Salter, 2007; Davalos et al., 2005; Nimmerjahn et al., 2005; Shehab et al., 2008; Shields et al., 2003).

Microglia express multiple receptors that may be involved in altering reactivity (Beggs and Salter, 2010) that include: P2X and P2Y purinergic receptors (Trang et al., 2009; Tsuda et al., 2003), TLR-4 receptors (Ji and Strichartz, 2004; Lehnardt et al., 2003), and chemokine receptors such as the fractalkine receptor CX3CR1 (Clark et al., 2011; Hughes et al., 2002), the CCR2 receptor for MCP-1/CCL2 (Thacker et al., 2009), and the IFN $\gamma$  receptor (Tsuda et al., 2009). Release of ATP, which acts via purinergic receptors, contributes to microglia changing to a reactive phenotype (Haynes et al., 2006). This is accompanied by morphological changes, increased proliferative capacity, and increased expression of membrane molecules such as complement receptor 3 (CD11b; Kreutzberg, 1996; Nakajima and Kohsaka, 1998) and Iba1 (Beggs and Salter, 2010).

Pro-inflammatory cytokines sensitize neurons by enhancing excitatory AMPA/NMDA currents and reducing inhibitory gamma-aminobutyric acid (GABA)/glycine currents (Kawasaki et al., 2008; Reeve et al., 2000; Sweitzer et al., 2001; Wang et al., 2005), but also contribute to neuropathic pain by stimulating microglia. Microglia are the main source of pro-inflammatory cytokines in the CNS (Hanisch, 2002) and increased functional microglial reactivity increases production and release of proinflammatory mediators (fractalkine IL-1 $\beta$ , IL-4, TNF $\alpha$ ), prostaglandins, and ATP (Giaume et al., 2007; Kreutzberg, 1996; Segond von Banchet et al., 2003; Watkins et al., 2001). Following receptor activation, an increase in the intracellular concentration of Ca<sup>2+</sup> activates signalling pathways, such as those mediated by the mitogen-activated protein kinase (MAPK) p38 (Ji and Suter, 2007) (Figure 7.1). p38 MAPK is a key factor in regulating the expression of proinflammatory cytokines, PGE<sub>2</sub> and COX-2 (Jana et al., 2003; Ji and Suter, 2007; Wilms et al., 2003), and is involved in the recruitment of microglia to areas of injury (Tsuda et al., 2005). p38 activation is increased following nerve damage, whereas its inhibition suppresses mechanical allodynia (Ji and Suter, 2007; Jin et al., 2003; Svensson et al., 2003). Activation of the transcription factor NF- $\kappa$ B also promotes the production of proinflammatory cytokines, chemokines, COX-2 and other molecules related to immune activity (Y.-J. Gao and Ji, 2010).

IL-6 is upregulated in both the DRG and the spinal cord after nerve injury (Raghavendra et al., 2003), and also has a dual function by stimulating microglia (Galiano et al., 2001; Klein et al., 1997) and neuronal responses to injury (Latrémoière et al., 2008).

### TLR4 receptor

The metabotropic receptor TLR-4 is important for pathogen recognition, and is activated by various substances, such as lipopolysaccharide from Gram-negative bacteria (H. Cao and Zhang, 2008; Capiralla et al., 2012). It is expressed on microglia and activation induces intracellular signalling cascades resulting in increased NF- $\kappa$ B signalling and subsequent expression of numerous genes regulating proinflammatory cytokines and other immunological molecules (Capiralla et al., 2012). Deficiency of this receptor or its blockade attenuates microglial reactivity, decreases levels of IFN $\gamma$ ,

IL-1 $\beta$ , and TNF, and reduces pain behaviours associated with PNI (Tanga et al., 2005).

### P2X<sub>4</sub> receptor

P2X<sub>4</sub> receptors are expressed by microglia following PNI (Tsuda et al., 2003). Blockade of this receptor prevents and reverses mechanical allodynia in animal models of PNI, and mice deficient in P2X<sub>4</sub> do not develop mechanical hypersensitivity after nerve injury (Ulmann et al., 2008). P2X<sub>4</sub>R expression is increased through the activation of other microglial receptors such as IFN $\gamma$  and fibronectin receptors (Masuda et al., 2012; Tsuda et al., 2008, 2009). P2X<sub>4</sub>R activation induces the synthesis and release of brain-derived neurotrophic factor (BDNF) by microglia (Coull et al., 2005; Trang et al., 2009) via a p38 MAPK-dependent pathway (Beggs and Salter, 2010; Jin et al., 2003). BDNF activates its neuronal receptor tyrosine kinase B (TrkB) on lamina I neurons in the spinal cord dorsal horn (Slack et al., 2005). This reduces the expression of the chloride transporter KCC2 leading to intracellular accumulation of Cl<sup>-</sup>. The net effect of this is disinhibition; reducing the inhibitory action of GABA, and facilitating further neuronal sensitization (Coull et al., 2003, 2005). BDNF signalling in neurons also activates kinase pathways leading to phosphorylation of the NMDA receptor NR1 subunit, which also contributes to enhanced sensitivity (Ren and Dubner, 2007; Suen et al., 1997).

### CX3CR1 receptor

Fractalkine (CX3CL1) is released by neurons and its receptor CX3CR1 is expressed on microglia, making it a prime candidate for neuronal-microglial signalling (Verge et al., 2004). The increased activity of primary afferents after nerve injury releases fractalkine into the extracellular space (Zhuang et al., 2007) and creates a chemotactic gradient for microglia (Chapman et al., 2000). Intrathecal injection of fractalkine upregulates expression of CX3CR1 and induces thermal hyperalgesia, which can be prevented by blocking fractalkine activity with CX3CR1 antibodies (Sun et al., 2007). Inhibiting microglial function with minocycline also prevents the appearance of mechanical allodynia and thermal hyperalgesia induced by injection of fractalkine (Milligan et al., 2005).

## Lymphocyte infiltration and central sensitization

In addition to increased macrophage and microglial reactivity following PNI, other immunocompetent cells, such as T-lymphocytes also play a role. T lymphocytes can release excitatory cytokines, generating ectopic impulse activity in sensory neurons after nerve injury (L. Cao and DeLeo 2008; L. Cao et al., 2009; Costigan et al., 2009; Hu and McLachlan 2002). The dorsal root ganglia have a small population of lymphocytes which perform an immune surveillance function (Hu and McLachlan 2002). Peripheral nerve damage causes infiltration of CD8<sup>+</sup> lymphocytes into the DRG and spinal cord (Costigan et al., 2009; Hu and McLachlan 2002) which suggests that PNI triggers an adaptive immune response. Moreover, this lymphocyte infiltration contributes to microglia reactivity via CD40 (a member of the TNF-receptor superfamily) (L. Cao et al., 2009) and mechanical hypersensitivity (Costigan et al., 2009; Hu and McLachlan 2002). The role of T cells is also demonstrated by

the reduction in pain behaviours after nerve injury exhibited by the lymphocyte deficient Rag1-null mice (Costigan et al., 2009).

## Postnatal differences in immune system activation after nerve injury

The role of neuroimmune interactions as mediators of neuropathic pain has focused on experimental models in adult animals. However, clinical studies suggest that traumatic nerve injury is less likely to produce neuropathic pain in early life; brachial plexus avulsion, which causes intense neuropathic pain in adults, is not painful when the injury is sustained at birth (Anand and Birch, 2002; see also Walker, Chapter 21, this volume). Laboratory studies conducted in animals throughout postnatal development are consistent with this: in nerve injury models of neuropathic pain, persistent mechanical allodynia does not develop if the injury is performed in the first 3 weeks of life, a developmental period which has parallels with human development from the neonate to adolescence (Howard et al., 2005; Ririe and Eisenach, 2006). Since infant rats and humans clearly respond to acute noxious stimuli and display both acute and chronic inflammatory pain behaviour from an early neonatal age, it appears that the mechanisms underlying neuropathic pain are differentially regulated over a prolonged postnatal period. Important differences include:

- ♦ Microglia in the neonatal spinal cord are capable of being activated by exogenous stimuli (e.g. intraspinal NMDA), but nerve injury in young rats fails to induce either the spinal microgliosis or macrophage accumulation in the DRG, that are hallmarks of PNI in the adult (Moss et al., 2007; Vega-Avelaira et al., 2007).
- ♦ Microarray analysis of gene expression in the DRG following nerve injury demonstrate changes associated with pro-inflammatory cytokines such as IL-6, CSF-1, and MCP-1 being upregulated in adult but not in young rats (Vega-Avelaira et al., 2009).
- ♦ In the spinal cord, many genes are differentially regulated in the adult compared with the infant rat, and the majority of these are involved in immune function (Costigan et al., 2009).
- ♦ Activation and infiltration of T-cells associated with the Th1 pro-inflammatory response in the dorsal horn is much greater in adult rats than in young animals after nerve injury (Costigan et al., 2009).

## Neonatal incision and long-term priming of microglial response

The mechanisms and effectors previously described, that are in place to mute the postnatal immune response as part of the normal developmental process, would at first suggest that early postnatal peripheral injury does not result in persistent neuropathic pain. While the incidence of neuropathic pain following traumatic nerve injury is lower in infants and young children, the concept that an absence of pain to early life injury indicates a lack of a response, whether CNS or immune, is simplistic. A key function that unites all sensory systems is that adult connectivity is shaped by the balance of sensory input in early postnatal life. In much the same way that auditory and visual system connectivity in the brain is driven by sound and light, tactile sense is driven by touch (Bourne, 2010; Sanes and Bao, 2009). Neural activity during critical postnatal periods can influence normal development (Hensch, 2004) and this is

also true for nociceptive pathways (Beggs et al., 2002; Ren et al., 2004). A considerable canon of evidence from both laboratory and clinical studies now shows that exposure to nociceptive stimuli in early life can produce long-term changes in sensory processing and the response to future injury (see Walker, Chapter 3; Grunau, Chapter 4, this volume). Importantly, priming of neuroimmune signalling by neonatal injury can contribute to persistent effects. 'Priming' or 'neonatal programming' of adult immune responses by early life immune stressors has been described (Boisse et al., 2004; Spencer et al., 2011), and an early immune challenge can alter pain sensitivity in adulthood (Boisse et al., 2005). As microglia are long-lived cells and can retain an innate immune memory (Perry, 2010) they are well suited to a role in persistent alterations. Plantar hindpaw incision, an established model of postoperative pain, performed during the first postnatal week, but not at older ages, enhances the response to subsequent injury 2 weeks later (Walker et al., 2009). The impact of neonatal injury persists until adulthood, with increases in both the degree and duration of incision-related hyperalgesia (Beggs et al., 2012a). These functional changes are mirrored by alterations in the time course and degree of microglial reactivity in the dorsal horn. The primed state arises from centrally-mediated changes in dorsal horn sensitivity or connectivity as:

- ♦ Hyperalgesia is selectively reversed by intrathecal minocycline, which reduces microglial reactivity in the spinal cord.
- ♦ The increased sensitivity and microglial reactivity following neonatal incision is also seen following direct electrical stimulation of the tibial nerve, which bypasses peripheral nociceptors (Beggs et al., 2012a).

## Conclusion

Interactions between the immune system and nociceptive pathways play an important role in modulating pain sensitivity. Throughout postnatal development, neuroimmune interactions have a significant impact on age-related changes in the response to PNI, and also play a role in persistent changes in future pain response following neonatal surgical injury. Evaluating the relative risks and benefits of modulating microglial activity to prevent long-term changes in nociceptive pathways, or to manage enhanced pain sensitivity states, requires further research.

## CHAPTER 8

---

# Central nociceptive pathways and descending modulation

Maria Fitzgerald

### Summary

Infants and children respond to noxious stimulation from birth, but these responses arise from neural activity at different levels of the central nervous system. Nociceptive activity at the level of the spinal cord or brainstem can produce reflex movements, autonomic and metabolic responses that may parallel pain, but cannot be equated with true pain experience. The key to pain experience lies in neural activation of central regions of the brain responsible for sensory discrimination and emotional responses. Thus higher centres in the brain allow noxious events to be discriminated from innocuous ones and create a sense of unpleasantness and threat. Laboratory and clinical studies are building up a picture of the functional connections in regions of the brain concerned with sensory and emotional aspects of pain at different stages of infant and child development. There is also increasing understanding of the maturation of endogenous control systems generated by the brain, which are likely to determine a child's ability to cope with pain. Furthermore, evidence is increasing that excess noxious stimulation in early life can alter the course of development of both central nociceptive pathways and descending modulation of pain.

### Introduction

Pain has many dimensions and is processed at multiple different levels of the nervous system. When tissue is injured in young individuals, it is essential that nociceptive pathways in the peripheral and central nervous system (CNS) are activated to stimulate protective behaviour and alert the attention of caregivers. Thus noxious stimulation stimulates reflex motor responses through circuits in the spinal cord and brainstem to ensure that the affected body region is protected from harm. In addition, autonomic circuits in the brainstem and hypothalamus are activated, to produce appropriate changes in the cardiovascular, respiratory, and endocrine systems and maintain homeostatic control of the body. It is these reactions that form the basis of paediatric clinical pain scores that measure movement, facial expression, cry, and other physiological indicators.

However, of great importance is not only the sensory discriminative, but also the emotional or affective component of pain, and the fact that it has a uniquely unpleasant and stressful quality and the potential to cause great suffering. As soon as a child is old enough for self-report, researchers and clinicians attempt to score the unpleasantness as well as the intensity of pain experience in order to better understand and alleviate the pain. The key to the maturation of this complete pain experience lies in neural activation of central subcortical and cortical regions of the brain and neuroscientists aim to map the nociceptive output from the spinal cord as it projects through ascending pathways, brainstem, and subcortical structures to the cerebral cortex and to investigate how different regions of the brain concerned with sensory and emotional aspects of pain become activated at different stages of infant and child development.

Another key determinant of pain experience is the activation of endogenous control mechanisms within the CNS that can modulate nociceptive activity through the release of endogenous opioids and a powerful system of pathways descending from the brainstem to the spinal cord. These descending and endogenous pain modulatory pathways are themselves controlled by subcortical and cortical networks and are the route by which factors such as attention and distraction, suggestion and expectation, stress and anxiety, context and past experience, can influence pain experience. Understanding the neural basis of developing endogenous descending pain control is as important as understanding ascending pain pathways, as this will influence a child's ability to cope with pain and the extent to which it may be manipulated.

Finally, the plasticity of these CNS pain pathways in infants and children is of great clinical importance. The formation of correct connections in sensory regions of the brain is highly dependent on an appropriate balance of sensory input from the periphery, and excessive noxious stimulation in childhood may alter the formation of cortical pain connections through neural activity-dependent mechanisms. Importantly, it may also change the normal balance of descending endogenous pain control, leaving an individual less able to cope with pain in the future.

In this chapter, the current state of knowledge of the development of central nociceptive pathways and descending controls is reviewed. Information has been gathered from laboratory studies in animal models and clinical and experimental investigations in infants and children. The picture is far from complete but this is a fast moving and important area of research.

## The developmental anatomy and physiology of central pain pathways

The development and maturation of neural connections in the brain are commonly mapped in the laboratory animals using anatomical, electrophysiological and behavioural techniques, and more recently, optogenetic stimulation of genetically controlled light-sensitive neurons. Knowledge gained from the laboratory can be combined with human data, from traditional autopsy studies and more recently, neurophysiological recording and imaging of the living human brain using structural and functional magnetic resonance imaging (fMRI) to provide an overall picture of the maturation of a particular pathway.

### Changing output from the spinal dorsal horn

Nociceptive information from the periphery is first integrated in the dorsal horn of the spinal cord (for the body) and trigeminal nuclei (for the head and neck). Multiple sensory afferent nerve fibres, carrying information from the skin, muscle, joints, deep tissues, and organs synapse onto single dorsal horn neurons resulting in spatial and modality convergence. Receptive fields of single dorsal horn neurons are larger and more overlapping than those of primary afferents, and multiple sensory modalities, such as touch and pinch, are processed by single 'wide dynamic range' (WDR) cells. However, there are also a smaller number of 'nociceptive-specific' (NS) cells in the dorsal horn that receive information only from nociceptive afferents. The vast majority of dorsal horn neurons are interneurons, connecting locally with other neurons in the same segment of the spinal cord, but a small percentage (*c.*5%), both WDR and NS, are 'projection' cells, that have long axons that travel up the spinal cord to higher centres in the CNS. Thus nociceptive information is transmitted partly by so-called 'labelled lines' devoted solely to nociception, and partly by multimodal pathways, where nociceptive information is coded by spatial and temporal patterns of neuronal activity.

Importantly, the proportion of WDR and NS neurons changes substantially with postnatal age (Fitzgerald and Jennings, 1999). The neonatal dorsal horn is dominated by low-threshold, tactile

inputs and although WDR and NS cells responding to nociceptive input can be recorded in the newborn rat dorsal horn, numbers are low in the first week and build up slowly (see Table 8.1).

Activity in dorsal horn networks ensure that spinal projection neurons transmit information to higher centres that is already substantially altered from the original afferent nociceptive input. Thus noxious information may have already been dampened down or amplified in magnitude and duration, through local interneuronal activity and central sensitization mechanisms both of which differ in young and adult animals (see Walker and Baccei, Chapter 6, this volume). It may also be modulated by descending inhibitory or excitatory influences arising in the brainstem that also change through postnatal development (see 'The development of descending brainstem modulation of nociception' section).

### Ascending spinal nociceptive projection pathways and cortical pain processing in adults

The cell bodies of dorsal horn projection neurons are found in superficial lamina I and deeper laminae VI to V and their long axons travel up the spinal cord in the contralateral spinothalamic tract (STT). Since the STT arises from WDR and NS cells, this tract does not exclusively transmit nociceptive information but also low-threshold tactile information and temperature sense. The thalamus is a major sensory integration centre and the information that thalamic neurons receive and send on to the cerebral cortex through thalamocortical tracts is essential for the awareness of pain. Nevertheless, it should be remembered that only 10% of STT axons directly terminate in the thalamus. Thus, while the classic termination site of STT axons in the ventral posterior nucleus (VPn) and other sensory nuclei in the thalamus (collectively called the ventrobasal complex) are commonly emphasized, most STT fibres also project to the brainstem reticular formation including the periaqueductal grey (PAG), the parabrachial nucleus (PBn), the locus coeruleus, and the hypothalamus (Gauriau and Bernard, 2004; Todd 2010).

The importance of these different pathways lies in the information that they subserve. Thus it appears that there is an anatomical basis for separating the sensory or nociceptive aspects of pain from its emotional or unpleasant aspects. Recent research has focused upon the projections of NS neurons in lamina I. Direct projections to thalamus are thought to mediate the sensory discriminative aspects of pain, while projections to the PAG and to the PBn, which in turn project to the hypothalamus and amygdala, are thought to mediate the emotional and autonomic aspects of pain.

**Table 8.1** Postnatal change in the proportion of rat dorsal horn cell responding to cutaneous noxious pinch, non-noxious brush or both (P = postnatal days).

Age	Dorsal horn cell response		
	Brush	Pinch	Brush and pinch
P3 (n = 22)	20 (91%)	1 (4.5%)	1 (4.5%)
P6 (n = 65)	54 (83%)	7 (11%)	4 (16%)
P10 (n = 53)	22 (42%)	12 (22%)	19 (36%)
P21 (n = 35)	10 (29%)	5 (14%)	20 (57%)

The output from the thalamus also appears to divide into two projections, a lateral and medial stream. While the lateral stream emanates from the thalamic ventroposterolateral nucleus (VPL) and projects directly to the primary somatosensory cortex (SI), a key cortical region for the sensory aspects of pain experience, the medial stream arises in the medial dorsal thalamic nuclei and projects to the secondary somatosensory cortex (SII) and the anterior cingulate and may contribute to the emotional aspects of pain (Willis et al., 2002).

Importantly, there is no 'pain' cortex, analogous to the visual or auditory cortex, rather noxious stimulation evokes a characteristic pattern of activity in many brain areas, including somatosensory, insular, and cingulate areas, as well as frontal and parietal areas. Coordinated activity in a collection of brain regions, none of which are unique to pain, are proposed to result in the multidimensional perception of pain. Other brain regions may be recruited to increase or reduce the intensity and unpleasantness of the pain in certain circumstances or in certain individuals (Apkarian et al., 2005; Tracey and Mantyh, 2007; Tracey and Johns, 2010). This is a rapidly changing area of pain research, however, with some controversy (LeGrain et al., 2011).

### **The development of ascending spinal nociceptive projection pathways to brainstem and thalamus**

STT neurons develop before birth in rodents: embryonic-day (E)-18, 2-day-old, and 1-week-old mice do not differ from adults in the number or distribution of STT neurons back-labelled from the thalamus although they significantly increase in size over the first postnatal week. Arborizations and boutons of STT neurons can also be observed within the ventrobasal complex of neonatal thalamus, suggesting that synaptic connections are formed with thalamic cells at this very early age (Davidson et al., 2010).

However, while anatomical connections to the thalamus may be present early in development, the functional maturation of nociceptive inputs to these regions is slower. The neural activity in subcortical brain areas has been mapped following formalin-induced injury to the paw using the neural activity marker, fos, in the brain of fetal and infant rats. By day 3, formalin evoked fos expression in the ventral lateral medulla (the site of origin of descending control pathways to the spinal cord), but not in subcortical areas responsible for signalling sensory and emotional information (namely the paraventricular and medial dorsal nuclei of the thalamus, the hypothalamus, and the PAG) which were all clearly labelled by 14 days of age (Barr, 2011). This developmental pattern may be related not only to the maturation of pain perception but also to development of autonomic and defensive reactions to pain in the infant (Chan et al., 2011).

Little is known about the development of the ascending STTs to the brainstem and thalamus in man although their presence is inferred from cortical activity in preterm infants (see later). Changes in facial expression in response to noxious stimulation are observed in extremely preterm infants, even in the presence of cerebral injury, suggesting direct functional nociceptive connections from the spinal cord to the brainstem at a very early age (Oberlander et al., 2002). Non-invasive diffusion tensor MRI and tractography in 1- to 4-month-old healthy infants show the spinothalamic tract and the corticospinal tract to be among the most mature bundles, while the most immature tracts are the internal capsule and cingulum (Dubois et al., 2008).

### **The development of thalamocortical connections—rodents**

While nociceptive activity in the spinal cord, brainstem, and subcortical midbrain structures are sufficient to generate reflex behaviours, autonomic and hormonal responses, they are not sufficient to support pain perception and awareness. Understanding the maturation of pain perception requires the study of supraspinal brain centres especially at the cortical level during early life.

A key step in the cortical processing of noxious stimuli is the development of thalamocortical projections. In rodents, thalamic axons leave the thalamus at E13.5 and begin to grow towards the subplate (SP) neurons, which are among the first born cortical neurons and reside at the white matter/cortical plate boundary. The SP zone, marginal zone, and cortical plate represent the early structures from which the layers of the cerebral cortex develop; the SP is largely transient, and the marginal zone forms layer I and cortical plate neurons form layers II to VI. Thalamocortical projections appear to exit the thalamus by E16 and form their first functional synaptic connections in the SP region around E18 to E19. By birth, thalamic axons are extending into layers IV, V, and VI of the developing cortex in a topographically precise manner and thalamocortical afferents and cortical sensory areas settle into place in the first week after birth. The refinement of topographical projections from the thalamus to the cortex is thought to arise through an activity-dependent process in which thalamic axons compete for cortical targets. If activity is altered during a critical period in early development, normal connectivity is disrupted. Synaptic connections are strengthened during development by correlated pre- and postsynaptic activity, and a likely mechanism for this process is N-methyl-D-aspartate receptor-dependent long-term potentiation (Li and Crair 2011). Cortical synaptic circuitry develops rapidly in the second postnatal week, simultaneous with experience-dependent turnover of dendritic spines. Patterned neuronal activity, such as spindle bursts in the neonatal cortex, promote the maturation of cortical synapses and neuronal circuits. Selective removal of SP neurons in the limb region of the somatosensory S1 cortex abolishes endogenous and sensory-evoked spindle burst activity and weakens thalamocortical inputs to layer 4 neurons. Thus, SP neurons are crucially involved in the generation of early network activity in the neonatal cortex, which is an important feature of cortical development (Tolner et al., 2012).

The maturation of transmission from thalamocortical connections takes place over a prolonged postnatal period. Thus a clear somatosensory-evoked potential from stimulation of the forepaw is not recorded until the end of the first week of life in rats and does not acquire a recognizably adult pattern until postnatal day (P) 12 (Thairu, 1971). An investigation of single cells in 7-day-old rat primary somatosensory cortex revealed low levels of spontaneous activity compared to adults and diminished excitability and longer latencies to cutaneous stimulation than in adults. In addition, receptive fields were considerably larger at 7 days, which reduces spatial discrimination. In contrast to adult cells, the immature cells commonly responded cyclically, with alternating phases of increased and decreased firing rate for periods of up to 3 s following punctate stimulation (Armstrong-James, 1975).

More complex functions in the cortex require linked activity in several areas, such as the pain matrix, carried out by large-scale

neuronal networks integrating several cortical areas. Little is known about the functional development of these networks and the maturational processes by which distant networks become functionally connected. Recordings across the whole cortical surface together with intracortical electrodes, reveals that sensory evoked cortical responses mature continuously throughout the first 3 weeks with the strongest developmental changes occurring in a very short time around postnatal day 13 (P13) (Quairiaux et al., 2011). This period, at the end of the second postnatal week coincides with the onset of mature pain behaviour (Fitzgerald, 2005), as well as major synaptic and functional changes within the S1 cortex.

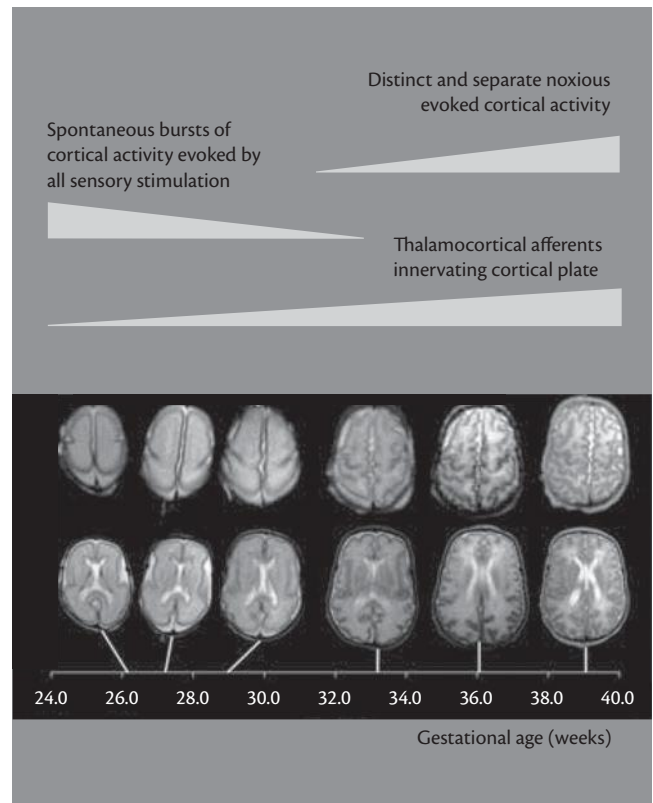

The neural circuitry of the medial prefrontal cortex (mPFC), an area of the brain that is key to assessing the threat of sensory stimuli and generating defensive responses, progressively develops more capacities as the animal matures. When rats are exposed to a threatening stimulus at P14, the mPFC is neither active nor responsive, but becomes responsive in processing aversive sensory stimulation at P26, and only finally regulates freezing in adolescence at P38 to P42 days (Chan et al., 2011).

### The development of thalamocortical connections—humans

The growth of thalamocortical afferents has been well documented in the human brain (Kostovic and Judas, 2010). In infants younger than 24 gestational weeks (GW), thalamocortical afferents are ‘waiting’ in a transient SP zone. These axons then penetrate the cortical plate between 24 and 26 GW and form functional synapses with layer IV cortical neurons beginning at 29 GW. The SP region gradually dissolves between 33 to 35 GW and after 36 GW there is a substantial growth and maturation of associative and callosal connections in the cortex (see Figure 8.1).

Results from a systematic fMRI study on mainly sedated preterm infants are consistent with the anatomical data and demonstrate well-localized blood oxygen level-dependent (BOLD) signal activity in the SI in response to balloon inflation of the hand in infants aged 25.5 to 34 GW. In this preterm group, positive BOLD activity to this proprioceptive and tactile stimulus was seen in the contralateral hemisphere only, while in preterm infants studied at term-corrected gestational age (36.5–41.5 weeks GA), the spatial distribution of the response was more complex with bilateral activity, and additional adjacent areas of negative BOLD signal change in the contralateral primary somatosensory and motor cortices. The results suggest that thalamocortical synapses carrying tactile information are functional by 25.5 weeks but more complex intra- and interhemispheric projections are not active until after 34 weeks GA (Arichi et al., 2010).

Functional connectivity magnetic resonance imaging (fcMRI) utilizes spontaneous, low-frequency (<0.1 Hz), coherent fluctuations in the BOLD signal to identify networks of functional cerebral connections and promises to be useful for mapping the development of key connections in the brain. Such mapping indicates that cortical hubs of connectivity in the newborn infant brain are largely targeted in the primary sensorimotor, auditory, and visual systems and only to a small extent in higher-order frontal, associative cortex (Fransson et al., 2011). However, the immature brain displays spontaneous patterns of electrical activity not seen in adults which may not be precursors of the spontaneous neuronal activity that forms

**Figure 8.1** The development of thalamocortical input and the changing pattern of somatosensory evoked activity in the human infant cortex over 24 to 40 weeks' gestation.

resting state networks in the adult; therefore fcMRI in this age group should be interpreted with care (Colonnese and Khasipov, 2012; see also Poorun and Slater, Chapter 39, this volume).

### The development of cortical pain processing

Advances in our knowledge of the onset of cortical pain processing in human infants and children have come through the application of imaging and electroencephalographic (EEG) measurements during clinical noxious procedures or in the presence of chronic pain.

Measurements of cerebral oxygenation have demonstrated that brief noxious stimulation (in the form of a heel lance for routine blood sampling) evokes a clear response in the contralateral somatosensory cortex of infants from 25 weeks postmenstrual age. Importantly, this cortical response is modality-specific, as non-noxious stimulation of the heel failed to evoke the response even when accompanied by a withdrawal reflex (Slater et al., 2006). Noxious inputs of longer duration may result in bilateral activation of the somatosensory cortex (Bartocci et al., 2006). These haemodynamic responses, which reflect a localized increase in total haemoglobin concentration, are caused by increased neuronal activity within the same area, as time-locked EEG recordings have demonstrated that the heel lance also evokes a clear nociceptive-specific potential in the infant cortex (Slater et al., 2010a). Furthermore EEG recording of noxious-evoked activity in infants

of different gestational ages has revealed how the brain begins to distinguish noxious information from innocuous tactile stimulation in early life (Fabrizi et al., 2011). Recording the brain neuronal activity in response to time-locked touches and clinically essential noxious lances of the heel in infants aged 28 to 45 weeks' gestation reveals a transition in brain response following tactile and noxious stimulation from non-specific, evenly dispersed neuronal bursts to modality-specific, localized, evoked potentials (see Figure 8.1). These recordings suggest that the haemodynamic recordings in very young infants reflect an increase in spontaneous burst responses, which is greater with noxious than tactile stimulation, but that the specific neural circuits necessary to distinguish the qualitative difference between touch and nociception emerge from 35 to 37 weeks' gestation in the human brain (Fabrizi et al., 2011).

The measurement of noxious-evoked brain activity in human infants has provided a valuable opportunity to determine the extent to which the clinical tools used to assess paediatric pain are correlated to the level of cortical activation following noxious stimulation. For example, facial expression correlates better with cortical haemodynamic activity than physiological responses such as heart rate, but cortical pain responses were observed in some infants in the absence of any change in facial expression following heel lance (Slater et al., 2008). In a double-blind, randomized controlled trial of oral sucrose, commonly used to reduce the behavioural response to painful procedures in neonatal intensive care, EEG and electromyographic recording revealed that sucrose does not significantly affect activity in neonatal brain or spinal cord nociceptive circuits (Slater et al., 2010a). This study suggests that the ability of sucrose to reduce clinical observational scores after noxious events in newborn infants is mediated at brainstem level.

Little information is available about the development of cortical pain processing in older infants and children. Childhood is a time of great change in the cerebral cortex: the highest number of dendritic spines in the dorsal prefrontal cortex is reached at 2.5 to 7 years and dendritic spine density in childhood exceeds adult values by two- to threefold and begins to decrease during puberty (Petanjek et al., 2011), but very little is known about how this influences the pain experience. The explosion of brain imaging studies examining the functional anatomy of pain processing in adults is gradually being extended to the paediatric population. A first, exploratory fMRI study of nociceptive processing in the cerebral cortex of thirteen 11- to 16-year-olds to tonic mild to moderately painful heat showed significant activation in somatosensory cortex, the anterior insula, the premotor cortex, and the prefrontal cortex (Hohmeister et al., 2010), all brain regions known to be activated by pain in adults (Apkarian, 2005). Activation of the anterior insula has been associated with pain affect while the prefrontal cortex activation has been related to cognitive aspects of pain processing, such as anticipation, attention, stimulus evaluation, and memory. Prefrontal cortex activation can modulate the pain experience and the premotor cortex has been linked to pain-evoked motor planning. Interestingly, these children did not show activation in the anterior cingulate, a region primarily involved in affective pain processing and modulation in adults (Hohmeister et al., 2010; see also Hermann, Chapter 40, this volume).

## The development of descending brainstem modulation of nociception

It has long been appreciated that the activation of descending pathways from brainstem regions, such as rostroventral medulla (RVM), can exert both inhibitory and facilitatory effects on spinal excitability and pain sensitivity in the adult (Heinricher et al., 2009). The RVM has strong inputs from the PAG which in turn is driven from the amygdala and other parts of the limbic system (see Figure 8.1). This is therefore the pathway that mediates top-down control of nociceptive input and pain, as has been elegantly demonstrated in man in imaging studies (Eippert et al., 2009; Tracey and Mantyh, 2007). However, laboratory studies have demonstrated that the maturation of this descending control is relatively late in development. Hence, in young animals, in the resting state, descending facilitation of spinal nociceptive processing dominates during the first weeks of life, with the typical biphasic descending facilitation and inhibition observed in adults not apparent until P28 (Hathway et al., 2009, 2012). The RVM, which is the main output nucleus for brainstem descending control, undergoes a remarkable maturational switch after P21: both lesioning and electrical stimulation of RVM at different postnatal ages reveal that RVM control over spinal nociceptive circuits switches from being entirely facilitatory before P21 to inhibitory at older ages. Between P25 and P35, descending inhibition begins to dominate, but it is not as powerful as in the adult until P40. Thus, the influence of the RVM over spinal nociceptive reflexes and dorsal horn neuronal activity gradually changes over this critical developmental period (Hathway et al., 2009). The delayed maturation of these inhibitory pathways from the RVM could explain why activating the PAG region (which sends extensive projections to the RVM) does not produce analgesia until P21 (van Praag and Frenk, 1991) or why stimulating the dorsolateral funiculus is unable to inhibit the firing of dorsal horn neurons or c-fos activation until at least P10 (Boucher et al., 1998; Fitzgerald and Koltzenburg, 1986).

The mechanism of change is likely to lie in the maturation of RVM and PAG circuitry, rather than in lack of descending connections, neurotransmitter levels, or receptor expression in the spinal cord. Interestingly, the postnatal development of inhibitory GABAergic neurons in the rat PAG matter mirrors the development of descending controls: very few such neurons are found from P0 to P5, with a small increase from P5 to P10, a marked maturation beginning at P14 and the adult pattern of GABA immunoreactivity only established between P20 to P30 (Barbarelli, 2010). The maturation of brainstem opioidergic signalling is also an important factor contributing to this developmental switch, as the switch also occurs when  $\mu$ -opioid receptor agonists are microinjected into the RVM suggesting that the descending facilitation of spinal nociception in young animals is mediated by  $\mu$ -opioid receptor pathways within the RVM. Furthermore, the developmental transition from descending facilitation to inhibition of pain is determined by activity in central opioid networks at a critical period of periadolescence (Hathway et al., 2012). Blockade of tonic opioidergic activity from P21 to P28, but not at earlier or later ages, prevents the normal development of descending RVM inhibitory control of spinal nociceptive reflexes, while enhancing opioidergic activity with chronic morphine over P7 to P14 accelerates this development. This change in control of supraspinal centres over spinal nociceptive reflexes and dorsal horn neuronal activity over a critical periadolescent

developmental period is likely to be of key importance in setting future pain sensitivity in adulthood.

## Plasticity of developing central nociceptive pathways

### Evidence in rodent brain

While it is well known that the development of central sensory pathways, such as the visual and auditory systems, is dependent upon a balance of sensory activity arising in the periphery, the absence of a clear 'pain' cortex and the complexity of regions activated during pain experience has meant that the influence of peripheral nociceptive activity in shaping the maturation of central pain pathways has been harder to establish, but evidence is rapidly emerging. Thus, rat pups that have received skin incisions in early life, not only have greater pain sensitivity to a repeat injury when they reach adulthood but also show differences in reward-related neural activity. Following exposure to a novelty-induced hypophagia paradigm (a test of motivation), fos activity in lateral hypothalamic orexin neurons, part of a specific reward seeking pathway in the brain, in acutely injured rats was the same as in uninjured naive animals but in those rats with a 'neonatal pain history', orexinergic activity was significantly increased and highly correlated with their motivational behaviour. Thus neonatal pain experience can cause long-term changes in brain motivational orexinergic pathways, known to modulate mesolimbic dopaminergic reward circuitry (Low et al., 2012).

Neonatal pain has also been shown to influence the generation of new neurons in the dentate gyrus region of the hippocampus. Rat pups receiving intraplantar injections of the painful inflammatory agent complete Freund's adjuvant, on P8, had more BrdU-labelled cells and a higher density of cells expressing doublecortin, both measures of newborn neurons, in the subgranular zone of the dentate gyrus, thought to be involved in memory formation (Leslie et al., 2011).

Descending pain control systems in the brainstem can also be influenced by early pain experience. Inflammatory pain induced by intraplantar carrageenan at birth induces significant changes in the brainstem endogenous opioid system into adulthood, namely increased beta-endorphin and met/leu-enkephalin protein levels and decreased opioid receptor expression in the PAG. These long-lasting alterations in endogenous opioid tone are likely to affect later pain sensitivity (Laprairie and Murphy, 2009). This is supported by the observation that focal electrical stimulation of the RVM in adult animals treated neonatally with carrageenan produced significantly greater descending inhibition of nociceptive responses to noxious thermal stimuli applied to the hindpaws and the tail, indicating that neonatal tissue injury and inflammation produces lasting alterations in descending modulatory systems that modify nociceptive processing (Zhang et al., 2010).

### Evidence in human brain—effects of neonatal intensive care

The developmental plasticity observed in laboratory animals is supported by structural and functional evidence of changes in the human infant brain following repeated noxious stimulation. Structural MRI studies suggest that procedural pain in the neonatal intensive care

unit can affect early brain development in preterm infants. Infants born very preterm (24–32 weeks GA) have been followed prospectively from birth and the number of skin-breaking events quantified to search for structural changes in their brain scans. After adjusting for clinical confounders such as illness severity, morphine exposure, brain injury, and surgery, the results show that greater neonatal procedural pain is associated with reduced measures of white matter and of subcortical grey matter. Reduced white matter was predicted by early pain, whereas grey matter changes were predicted by pain exposure throughout the neonatal course, suggesting a primary early effect on subcortical structures, such as the thalamus, followed by secondary white matter reductions (Brummelte et al., 2012; see also Grunau, Chapter 4, this volume).

Infants who are born prematurely and who have experienced at least 40 days of intensive or special care also have increased brain neuronal responses to noxious stimuli compared to healthy newborns at the same postmenstrual age. Evoked potentials generated by noxious clinically-essential heel lances are significantly larger in prematurely-born infants, while responses to non-noxious touch stimuli are unaffected, suggesting a functional change in pain processing in the brain (Slater et al., 2010b). FMRI of cerebral pain responses in a similar cohort of preterm infants when they have reached school-age (11–16 years) show that aside from more general neurodevelopmental consequences, repeated neonatal nociceptive input may result in continued increased sensitivity in central pain pathways into adolescence. Tonic heat stimuli (of individually adjusted moderate pain intensity) applied to the ex-preterm children causes significant activation in the thalamus, anterior cingulate cortex, cerebellum, basal ganglia, and PAG that is not observed in full-term hospitalized children or controls. The preterms also show significantly higher activation in the S1, anterior cingulate cortex, and insula than controls. This exaggerated brain response is pain specific and is not observed during non-painful warmth stimulation (Hohmeister et al., 2010).

There is also evidence that neonatal intensive care can alter endogenous descending control systems. Children, aged between 7 and 11 years, divided into term, preterm exposed to numerous painful interventions, or preterm exposed to few painful interventions, have comparable pain thresholds but differ in their responses to conditioning cold stimulation. Thus while cold stimulation significantly increases heart rate and decreases thermal pain sensitivity of term-born children and 'preterm less pain' children, changes in heart rate and pain sensitivity in response to conditioning cold stimulation were not observed in 'preterm more pain' children. These results suggest that endogenous pain modulatory mechanisms are not as well developed as those of children not exposed to noxious insult at birth (Goffaux et al., 2008; Wollgarten-Hadamek et al., 2011).

### Evidence in human brain—paediatric chronic pain

Evidence suggests that central changes in the brain can occur in older children who develop chronic pain syndromes. Children with migraine when undertaking an experimental attentional task, display EEG activity associated with an automatic attentional bias towards painful and potentially painful somatosensory stimuli, perhaps due to alterations in connectivity within the limbic system (Zohsel et al., 2008).

CNS activation to sensory stimulation in paediatric patients (9–18 years) with complex regional pain syndrome (CRPS) affecting

the lower extremity also reveals changes. In an fMRI study each patient underwent two scanning sessions: once during an active period of pain (CRPS(+)), and once after symptomatic recovery (CRPS(-)). In each session, mechanical (brush) and thermal (cold) stimuli were applied to the affected region of the involved limb and the corresponding mirror region of the unaffected limb. Several interesting observations were made in this study but notably in the CRPS(-) state, significant activation differences persist despite nearly complete elimination of evoked pain suggesting prolonged changes in CNS pain circuitry in paediatric patients with CRPS that outlast the illness itself (Lebel et al., 2008).

There is an urgent need for more investigative studies of pain processing in the brains of children. Despite the ethical and practical challenges that such studies present, it is important to allow children to participate in well-designed research studies so that they can benefit from research advances to the same degree as adult populations (Sava et al., 2009).

# Psychological theories and biopsychosocial models in paediatric pain

Rebecca Pillai Riddell, Nicole M. Racine, Kenneth D. Craig, and Lauren Campbell

### Summary

The purpose of this chapter is to review existing biopsychosocial models of paediatric pain and to examine common key factors across different theoretical conceptualizations. Critical gaps in the empirical and theoretical literature are elucidated. In particular, lack of specific attention to developmental factors in biological, behavioural, and social functioning and the need for models that examine gaps in different types of pain responding (e.g. immediate acute pain response, acute pain responding in the context of chronic pain) are highlighted. Moreover, the need for comprehensive, conceptual models, representative of current knowledge, that readily generate specific hypotheses confirmable by experimentation are also discussed as ways of moving the field of paediatric pain forward, both conceptually and pragmatically.

### Introduction

Except in very rare cases of congenital insensitivity, pain is inevitable and ubiquitous in the lives of children. Despite its universality, the complexity of any child or adult's actual experience of pain remains elusive to others, given its subjective nature. Nevertheless, the established deleterious impact of unmanaged pain during childhood on biological, psychological, and social well-being (Anand, 2000; Fitzgerald, 2005; Grunau, 2006; Hohmeister et al., 2010; Taddio et al., 1997) dictates a necessity to better understanding of not only the 'ever-elusive' pain experience but also how the more easily quantifiable 'pain expression' contributes to understanding the experience, assessment, and management of paediatric pain.

The complexity of different pain experiences (e.g. acute, acute-prolonged, chronic) and the varying importance of both broader system factors (medical staff, cultural norms) and more narrow system factors (such as parents and peers) have led to diverse frameworks in understanding the interplay of biopsychosocial factors in paediatric pain. Having biopsychosocial models help scientists and clinicians attempt to discern and integrate the multifaceted pieces to

approximate an understanding of the complex enigma of another's pain. In addition to comprehensiveness of bio-, psycho-, and social variables, ideally good models should represent current scientific knowledge in the field and generate new ideas that can be subjected to empirical validation. This chapter will review key models in the field and discuss their content in terms of comprehensiveness, representativeness, and potential for novel hypothesis generation.

### The first biopsychosocial model of pain: gate control theory

A review of theoretical models would be incomplete without mentioning the road the gate control theory of pain paved for modern transdisciplinary models of pain. Moving away from antiquated dualistic conceptualizations of pain as existing in the mind or the body and building upon current knowledge in the field, Melzack and Wall (1965) proposed a groundbreaking model that included testable mechanisms bridging the interplay between psychosocial and biological features of the pain experience. One of the key landmark implications of gate control theory and the subsequent neuro-matrix theory for researchers and clinicians was the central role of the brain in processing and representing noxious stimuli (Melzack, 1996, 1999). Ushering pain research into the modern age, the realization that 'without the brain there would not be pain' became a fundamental principle of pain research. Moreover, with recognition that pain is substantially more than mere sensory experience, theoretical models broadened their scope to include diverse factors implicated in pain experience, i.e. biological substrates, internal cognitive/affective/biological schema, social, and environmental (Craig et al., 1996). Despite minor criticisms that have been put forward including that pain inhibition is much more complicated than laid out in gate control, by recognizing the primacy of the brain as the *active* recipient of noxious input and by specifying testable mechanisms that addressed both biological and psychosocial dimensions, these models set the stage for research proliferation in the field of pain that continues to this day. In addition, it also

fostered the development of more targeted biopsychosocial models of pain. It was recently asserted that the prospects of advances in clinical assessment and management of children's pain are best served by comprehensive models that are inclusive of all determinants (Hadjistavropoulos et al., 2011).

While not biopsychosocial in scope, two other theories should be discussed at the outset due to their integral role in modern theories of paediatric pain. Both operant conditioning and social learning models have set a foundation in which to help operationalize the psychological and the social aspects for current biopsychosocial conceptualizations.

## **Operant and social learning models of paediatric pain**

Operant models of pain have been extensively used to understand chronic pain in the adult pain literature (Fordyce, 1976). The application to paediatric pain came onto the scene later. Turk and colleagues (1987) conducted one of the first reviews on the involvement of the family on child chronic pain. They discussed the concept of 'painful families', which are families where there is an increased incidence of chronic pain problems. Ultimately, they concluded that the family plays a major role as an agent of positive and negative reinforcement. The child's pain behaviours (e.g. crying, moaning) can be strengthened or extinguished depending on environmental responses. Reinforcement may be particularly salient for children with chronic pain since parent behaviours, such as attending to pain behaviours and granting permission to avoid daily activities, are related to higher levels of illness behaviours in children with recurrent abdominal pain (Walker and Zeman, 1992). A more recent review has also highlighted the contribution of operant conditioning on paediatric chronic pain and put forward an integrative model (discussed fully later in this chapter) of factors impacting on paediatric chronic pain, including individual variables such as parental reinforcement and solicitousness (Palermo and Chambers, 2005).

While reinforcement and punishment are key aspects to understanding how paediatric pain responses develop and are maintained, by nature the theory tends to focus on more narrow contributors that are temporally linked to the pain response without expounding other aspects of environmental learning such as through observation and modelling. Social learning theory is a broader approach to learning emphasizing not only child factors related to their appraisal of a painful situation but also familial/larger system influences on how to think about and act when in pain (Williams et al., 2011).

Social learning theory puts forward that children learn within a social context, which is facilitated by modelling and observation (Bandura, 1977). According to social learning theory children learn behaviour by observing others and imitating what they have observed. Moreover, whether the behaviour is imitated and learned depends on the salience of the model and the consequence of the behaviour. The child is also more likely to exhibit the learned behaviour if he or she believes that the pain behaviour will lead to a specific response from their support network (Osborne et al., 1989). An example of social learning was demonstrated in a study that found that children of chronic low-back pain patients exhibited a higher frequency of similar pain behaviours when they had a parent with a chronic pain condition versus when they had parents who were healthy or diabetic (Rickard, 1988).

While much social learning literature has focused on paediatric chronic pain, Page and Blanchette argue that social learning theory is also a useful perspective from which to understand paediatric procedural pain (2009). For example, work by Chambers and colleagues demonstrated that positive reinforcement and modelling of pain behaviours by parents during an acute pain task had an impact on child pain behaviour, particularly for girls. Girls whose mothers demonstrated pain-promoting behaviours reported more pain than girls whose mothers did not react in the same manner (Chambers et al., 2002). Social learning theory is also relevant to paediatric procedural pain because of the roles anticipatory anxiety and avoidance play in pain responses (Page and Blanchette, 2009). Children may display anticipatory anxiety or avoidance because they believe they will be unable to manage the procedure. Social learning theory is a useful model through which to understand the development and maintenance of child pain behaviour in both acute and chronic pain contexts. As will become apparent, social learning contributes, either overtly or covertly, to the psychosocial foundation for all biopsychosocial models presented in this chapter.

The current review found that biopsychosocial models of paediatric pain fell into two broad categories: (1) a small and relatively recent literature specifically addressing chronic pain and (2) a much more developed literature examining acute procedural pain. The following examines these two broad categories, including a more detailed section on the social communication model (SCM) of pain as this model is one of the most widely cited explanatory models in the field of paediatric pain. We begin our discussion of biopsychosocial models by tackling paediatric chronic pain.

## **Biopsychosocial models of paediatric chronic pain: theoretical beginnings**

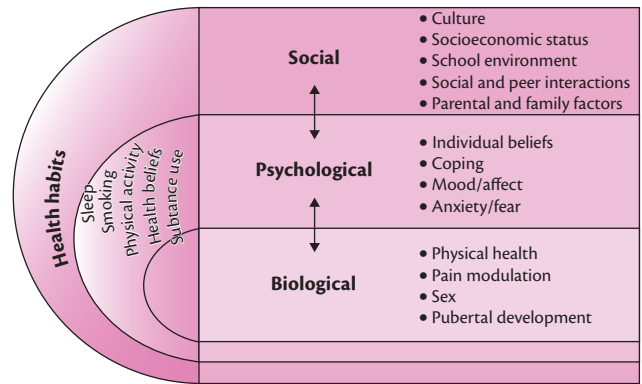

Rather than defining chronic pain in terms of duration, current conceptualizations base the distinction between chronic and acute pain on functionality (Woolf, 2010). Acute nociceptive pain serves to warn the organism of real or imminent tissue damage, whereas persistent pain diminishes or prevents movement and can promote healing. Within the broad domain of persistent pain one can identify chronic pain that is pathological because it serves neither function and would appear to be the consequence of an abnormally functioning or damaged nervous system. Neuropathic pain best illustrates the latter. A recent epidemiological review of chronic pain during childhood and adolescence described many different types of chronic pain (e.g. headache, back pain, musculoskeletal pain), with median reports of prevalence ranging between 11% and 38% of the populations studied (King et al., 2011). However, most of the studies reviewed used 'duration of pain' to classify children's reports of pain as chronic. A commentary on this review suggested that probably 5% to 15% of children suffer from chronic pain that is disabling and requires professional intervention (von Baeyer, 2011).

Clearly significant numbers of children suffer from chronic pain, thus, models of this pain type need to assist clinicians and researchers in understanding why a subsample of children come to report disabling chronic pain when others do not. One must turn to formulations of how biological endowment and maturation interact with the physical and social environment to appreciate the emergence of individual differences in the experience and expression of pain and disability.

## An integrative conceptual model for understanding paediatric chronic pain and disability

There have been recent attempts to describe interactions among biological, psychological, and social features and/or determinants of children's chronically painful conditions. In their 'integrative model of parent and family factors in paediatric chronic pain and associated disability', Palermo and Chambers (2005) focused on the psychosocial component of the biopsychosocial perspective. They describe operant-behavioural perspectives of parent-child interaction within the broader framework of family systems theories. Individual parenting variables, such as parenting style or parental reinforcement of child pain behaviours, are recognized as important within the context of dyadic interactions with the child. For example, the quality of the parent-child interactions, which in turn are nested within broader family-level variables, such as family cohesion or overall functioning, were outlined. Specific child variables, such as the level or nature of pain or disability, or moderating/mediating variables, such as the child's gender, age, emotional status, and coping, are hypothesized to influence the family, dyadic, and individual variables. In this model, complex bidirectional relationships are proposed between the aforementioned nested variables and paediatric chronic pain, such that not only do parenting, dyadic, and family-level variables influence paediatric chronic pain, but paediatric pain would have an impact on family dyadic interactions and overall functioning. This model emphasizes the developmental context of these complex and bidirectional relationships and the dynamic, progressive nature of changes in relationships. Thus, there is an emphasis on recognizing that the specific variables of interest would vary with the developmental status of the child and contribute to developmentally appropriate care. Ultimately, the model emphasizes the mutually influencing relationship between the family unit's functioning (both the whole system and multiple subsystems within) and the child's pain, functional disability and the variables that moderate or mediate the relationship between the two. In this model, psychosocial factors within the narrow family system are handled well because the model accurately reflects current knowledge on this topic. This is clearly seen in the specification of potential mediators/moderators that may influence the relationship between pain and functional disability. However, although not its set out purpose, in terms of comprehensiveness, it does not go beyond immediate family factors (such as medical systems and cultural norms) and does not look at the interplay with biological factors within the child. Moreover, the actual relative relationships among individual, parent, and family factors on chronic pain/functional disability are vague.

Palermo (2012) extended the theoretical foundation proposed by Palermo and Chambers (2005) by explicitly adding in new components to the model, namely: (1) biological processes, (2) the dimension of psychological factors influencing health habits, and (3) social factors that go beyond consideration of parents and the family. The 'guiding conceptual model for understanding paediatric chronic pain and disability' (see Figure 9.1) is therefore more comprehensive in its scope. In terms of the biological levels of influence, consideration was given to ontogenetic maturation, including genetic factors, central nervous system functioning, sex, and pubertal status. Psychological variables proposed as important in paediatric chronic pain include individual beliefs, coping, mood/affect, anxiety, and fear. Broader social variables, such as culture,

socioeconomic status, school environment, and characteristics of the health care system, were recognized as providing context for the more proximal family and parent social factors. A novel aspect of this model is close examination of the role of health habits (such as sleep, physical activity, substance use) play in paediatric chronic pain and disability. Explicitly making stable health habits salient highlights the importance of assessing these peripheral but fundamental behaviours because of their potential role in moderating pain and disability, particularly in older children and adolescents. This model posits bidirectional relationships among biological, psychological, and social factors with biological factors nested within the psychological context of the child, which in turn is nested within social contexts. Health habits would develop on the basis of the interplay of all three factors. Developmental considerations are advanced in this model, with the biology of pubertal development highlighted as particularly important. Reflective of current research in the broader field of paediatric psychology, the innovation of including health habits are noted as particularly relevant in adolescent populations. The model is broad in scope and describes an interplay of different aspects of the systems. However, while the comprehensiveness and representativeness of the model facilitates a broad inventory of potential factors in chronic pain, this appears to come at the cost of its specific predictive power. Specific hypotheses about how factors within different systems interact for empirical validation purposes (e.g. mood, culture, and puberty) and the directionality of these relationships are not readily evident from the model descriptions.

As discussed earlier, integrative models in the area of paediatric chronic pain are still in their early stages, with modelling typically representing the product of a particular investigative group. In contrast, paediatric models of acute pain began proliferating about a decade earlier and have had the benefit of diverse viewpoints on the topic. The following section addresses a number of recent models.

## Biopsychosocial models of paediatric acute pain

Contrary to the dearth of theoretical literature on paediatric chronic pain, several models that specifically address acute or procedural paediatric pain have been advanced in the paediatric pain

literature. In all of these models, the proposed relationships and interplay between variables are presented in the context of a particular painful episode (e.g. a specific immunization or other painful medical procedure).

### **A social-ecological framework for understanding procedure pain**

Informed and laid out similarly to Bronfenbrenner's (1977) social-ecological framework, Kazak and Kunin-Batson's (2001) model situated the child in pain at the centre of a series of nested concentric circles representing the increasingly broad social settings that have an impact on a child in pain and that exert bidirectional influences on the child. Contained in the first circle of influence, the microsystem, are child-specific, or intrapersonal, factors such as age, biology, coping, health, and the pain experience itself. In the mesosystem, or second circle of influence, are social factors in the child's immediate life contexts, such as those relating to family, peers, school staff, and hospital staff, and the interrelationships between these social units. Finally, broader social environments are represented by the largest circle of influence or the exosystem, such as social networks of parents, ethnocultural influences, including cultural beliefs and practices, health care systems, and public policy. The interpersonal meso- and exosystems are hypothesized to exert a direct and indirect impact on the child in pain (the microsystem) and all three systems are expected to interact, a position this perspective shares with other models discussed. Once again, the model, while comprehensive in its scope and grounded in current research, has limited impact beyond providing a comprehensive description of potential variables related to procedural pain. In essence, specific hypothesis testing of the dynamic interplay of nested spheres is impossible because of the large number of interactive possibilities that different factors within different spheres present.

### **Stimulus–response model of (paediatric) pain**

The 'stimulus–response model of (paediatric) pain' (Cohen et al., 2008) takes a different perspective by structuring the model around a linear sequence of events that follow a specific painful stimulus (e.g. injection, inflammation). First, there is a short-term response phase in which pain, distress, and anxiety can be experienced, but also in which the opportunity to learn, practice, cope, or be coached exists. The link between the painful stimulus and the short-term response is hypothesized to be modulated by child factors (e.g. coping behaviours, prior experiences), parent factors (e.g. coaching behaviours, parent anxiety), medical staff factors (e.g. coaching behaviours, staff anxiety), and contextual factors (e.g. environmental factors, culture). Following this short-term response phase is the long-term response phase in which health attitudes/behaviours, distress memories, and expectations can develop, physiological changes can occur, and the opportunity to cope or be coached exists. Similar to the link between the painful stimulus and the short-term response phase, the link between the short-term response phase and the long-term response phase is hypothesized to be modulated by the same child, parent, medical staff, and contextual factors discussed earlier. In line with a biopsychosocial approach to understanding paediatric pain, this model addresses biological, psychological, and social spheres of influence, as well as the interplay between the specific variables that subsume these three levels. Compared to earlier models discussed previously, this model does not overtly hypothesize a transactional, or bidirectional, relationship

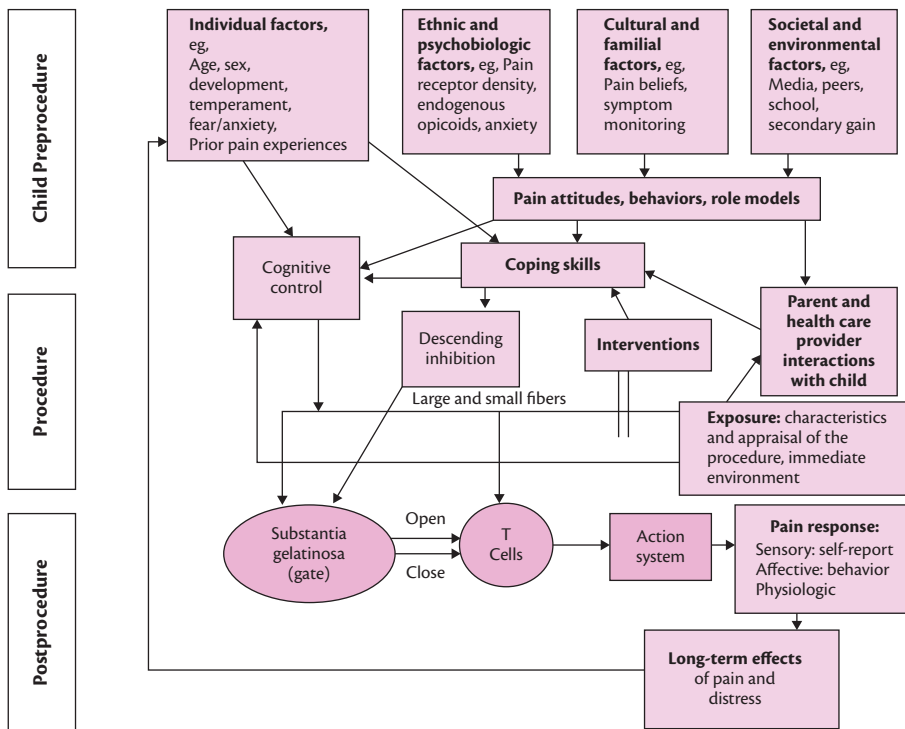

among features and determinants of the pain experience choosing rather to specifically outlay the directionality of certain relationships. However, with this model we see a different type of limitation in that while specific mechanisms are readily identifiable and testable, potential gaps in the conceptualization of relationships between variables are evident. For example, whereas it is hypothesized that child factors (such as coping behaviours) or parent factors (such as anxiety) can modulate the child's short-term pain response or long-term distress memories, the model does not explicitly propose that the child's short-term pain response or long-term distress memories would exert influence on the child's coping behaviours or the parent's anxiety. Moreover, it provides only a surface treatment of biological variables and a more comprehensive integration of biological factors would improve its conceptual value.

### **Young's model of paediatric procedural pain**

Similarly to Cohen's model, Young's (2005; see Figure 9.2) biopsychosocial model contextualizes paediatric procedural acute pain by first breaking the time sequence of a procedural pain event into three phases: (1) pre-procedure, (2) procedure, and (3) post-procedure. This framework acknowledges that while acute pain occurs in a distinct episode of time (procedure), it is substantially influenced by pre-procedural factors, such as the mindset the child brings to the procedure (memories of past pain, fear/anxiety, temperament), unique biological dispositions (such as pain receptor density, endogenous opioids), and social influences (such as parental modelling, cultural beliefs, media attention, peer influences). Furthermore, the cumulative impact of both pre-procedural and procedural factors would continue to influence the child after the procedure has been completed. Similar observations must apply to acute pain arising from injury. Importantly, this model stands alone from models reviewed thus far by including a specific feedback loop postulating that after the procedural pain response, long-term effects of pain and distress (such as memories of the acutely painful experience) will in turn directly impact on an individual's cognitive control and coping skills in the next painful experience.

In addition, the model explicitly incorporates Melzack and Wall's (1965) gate control theory by noting that both individual (such as age, sex, development, and temperament) and other systemic factors (such as ethnicity/psychobiological factors, cultural/familial factors, and societal/environmental factors) impact on central cortical control processes and descending inhibitory mechanisms of the pain gate, which in turn determine the pain response (sensory, affective, and physiological).

Given such a broad array of factors and clearly laid out interrelationships, the potential for contributing to the development of the field becomes readily apparent. When critically appraising the model, questions quickly arise regarding interactions among specific subunits of the model. For example, why is a child's pain and distress presumed to only impact on individual factors but not psychobiological factors such as pain thresholds? Additionally, given the integral role of ongoing threat appraisals in the actual pain response, pain responding (in particular physiological responding) would also be directly impacted upon by pre-procedural factors such as previous pain experiences, rather than solely being mediated by a child's cognitive abilities and schemas. It is notable that the various mechanisms and constructs describing the pain response are laid out explicitly. Hence, this model provides clear avenues for empirical validation and its in-depth empirical basis is clearly

**Figure 9.2** Model for conceptualizing and studying paediatric procedural pain (Young, 2005). Reprinted from *Annals of Emergency Medicine*, Volume 45, Issue 2, Kelly D. Young, Pediatric Procedural Pain, pp. 160–171, Copyright © 2005, with permission from Elsevier, <http://www.sciencedirect.com/science/journal/01960644>

laid out in the paper. One conceptual criticism of the model is that the caregiver of child in pain appears to be relegated to a peripheral role during the procedural phase and is not acknowledged as having a direct impact on the child's construction of previous pain experiences.

### The social communication model of pain

In a hybrid approach that incorporates the sequencing of events in acute pain and yet acknowledges larger spheres of both inter- and intrapersonal influence, Craig and colleagues have taken a broader perspective that emphasizes social learning theory in how the child, the caregiver, and the relationship function in the pain context (see Figure 9.3). The focus is upon dyadic interactions between the child and others, but consideration is given to the broader social ecological systems within which child pain is suffered. Having had the benefit of over a decade of development, including exploration of its empirical and theoretical ramifications (e.g. Craig, 2009; Craig et al., 1996; Hadjistavropoulos et al., 2011), the conceptual framework now provides by far the most developed biopsychosocial formulation of paediatric acute pain. It predates other models described here with the first paediatric version released in the early 1990s when the importance of the social context to understanding children in pain was only beginning to be established.

Important and relatively unique features of the SCM include the impact of socialization on child pain experience and expression as well as the inclusion of persons other than the individual experiencing the pain, caregivers in particular. This is particularly important in paediatric pain because vulnerable infants and children are heavily reliant on family, other adults, and professionals for caregiving, including assessment and relief from pain (Pillai Riddell and Racine, 2009). The SCM as it relates to paediatric pain includes processes whereby the subjective pain experience of the child is transduced into a pain expression that can be assessed by

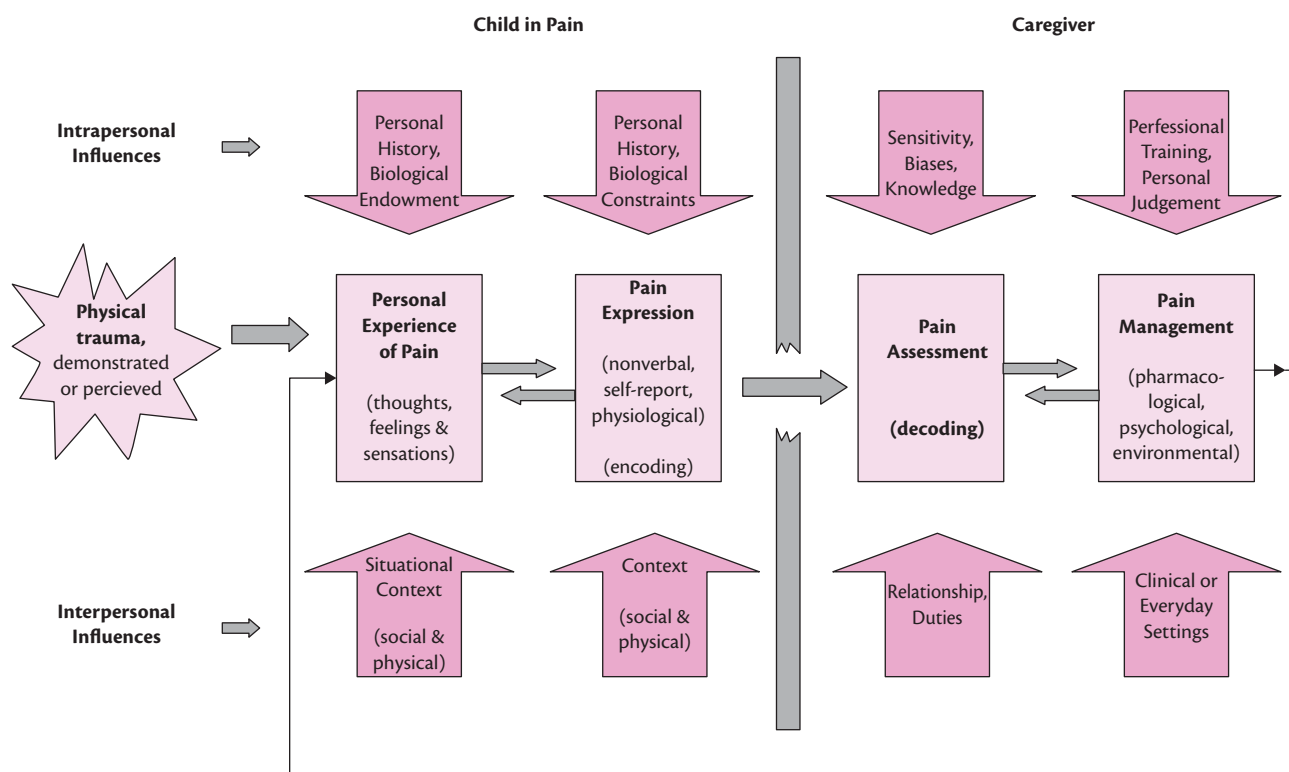

caregivers who, when deemed necessary, will take action to manage the pain.

These transactions between the child and persons in the social environment are explicitly examined during four sequenced, conceptually distinct but interactive stages following an initial painful event: (1) the child's pain experience, (2) the child's pain expression, (3) assessment of pain by a caregiver, and (4) actions taken (or not taken) by others that would impact on the child's pain.

Thus, when tissue damage or trauma occurs, the noxious input is transduced into the child's perception of pain. The biological dispositions triggered are the outcome of the biological, personal, and social history of the child, not only the nociceptive sensory input. The experience includes both automatic/reflexive features as well as higher level processing reflecting the learning history of the child. Thus, an understanding of the reaction to a noxious event, whether acute tissue trauma or exacerbation of chronic pain, requires consideration of both immediate and personal history events.

The second stage concerns the complexities of how painful experience becomes manifest in the expression of pain. Pain expression may be observed in infants vocally through crying or screaming, as well as through non-vocal expression, including facial expression and body actions. Depending on the developmental stage of the child, they may be able to use language to communicate pain. There are bidirectional relationships between pain experience and pain expression, whereby the child's pain experience will impact on pain expression, and a child's expression of pain will impact on how it is experienced. The distinction between the experience and expression of pain implicitly acknowledges they may be discordant. This complicates the challenge caregivers confront when attempting to assess a child's distress, with decisions about an appropriate course of action depending upon this judgement.

Pain expression and caregiver assessments mutually influence each other. Pain expression primarily, but not exclusively,

**Figure 9.3** The social communication model of pain. A conceptual biopsychosocial model depicting the interaction between the child in pain and their caregiver. Reprinted with permission from Craig, K. D., The social communication model of pain, *Canadian Psychology*, Volume 50, pp. 22–32, Copyright © 2009, American Psychological Association. DOI: 10.1037/a0014772.

determines the observer's pain assessment, and this reaction in turn will have an impact on the pain expression (and experience) depending upon the reaction. The component of the model encompassing child expression and caregiver assessment is at the heart of the model and exemplifies the belief that pain is fundamentally a social experience. Pain was evolutionarily conserved as a biological adaptation, with expression and adult reactions to the child playing no small part. Children modulate signals of pain and distress contingent upon perception of the immediate context, including receptivity of the caregiver, and the caregiver would also attune sensitivity to signals based on their interpretation of the child's expressivity. Parental and health practitioner sensitivity as social determinants of children's pain expression seem obvious and would not seem to require further illustration here.

Finally, the caregiver's assessment of the urgency, intensity, and necessity of the pain signal determine whether the caregiver will take action and attempt to control pain. As with all phases of the process, caregiver judgements and decisions to provide care are mutually influential. The actions a caregiver takes may also impact on their assessment (e.g. if the actions are effective, the assessment might be that the pain is lower). Moreover, how a caregiver manages a child's pain will also feed back to the beginning of the sequence and impact on how a child's pain experience is constructed. These four steps delineate the dynamic interaction between children and caregivers in the paediatric pain context.

Upon review, four key features of the model contribute to its explanatory value. First, the model characterizes important

interactions between the child in pain and her/his caregivers. Social learning approaches to child development in a pain context, including both operant (e.g. Gatzounis et al., 2012) and observational learning (e.g. Goubert et al., 2011) processes have proven particularly useful in model refining. Second, the model examines a progression of four stages following onset of painful events that first concern the child and then the caregiver (see later). Third, the SCM recognizes dynamic reciprocal relationships between the infant's or child's experience and communication of pain and the caregiver's interpretation and reaction to the pain-related distress. Finally, as the model developed, intrapersonal and interpersonal factors unique to the biological and environmental history and current status of the individual child and caregiver were shown to be crucial to understanding the child and the caregiver, separately and interactively.

As aforementioned, the SCM has provided rich fodder for empirical work in the field trying to elucidate the psychosocial influences on paediatric pain. However, in contrast to more focused models of paediatric procedural acute pain (such as Young's model), the SCM is not ideally suited to provide detailed guidance regarding specific mechanisms subsuming the interplay between components. It provides broader conceptual guidance postulating the general sequence of acute pain from painful trigger to caregiver management and outlining the spheres of influence with specific mention of potential variables on each step of the sequence. The differing approaches, while overlapping, tend to generate different types of hypotheses. For example, while both models suggest previous

pain history impacts on a child's pain response, the SCM postulates that it impacts on the experience of pain which in turn impacts on expression, while the Young model suggests a more specified feedback loop such that previous experience impacts on current experience via the child's cognitive control exerted over the pain gate pathways and via the child's coping skills, which both in turn impact on current pain experience and then, subsequently, future pain experience. One final criticism of all paediatric pain models presented to date, whether they focus on the sequence of events, the larger spheres of influence, or both, is the lack of specific attention to the developmental stage of the child—a key variable in understanding paediatric pain.

### A biopsychosocial model specifically for infant pain: the DIAPR model

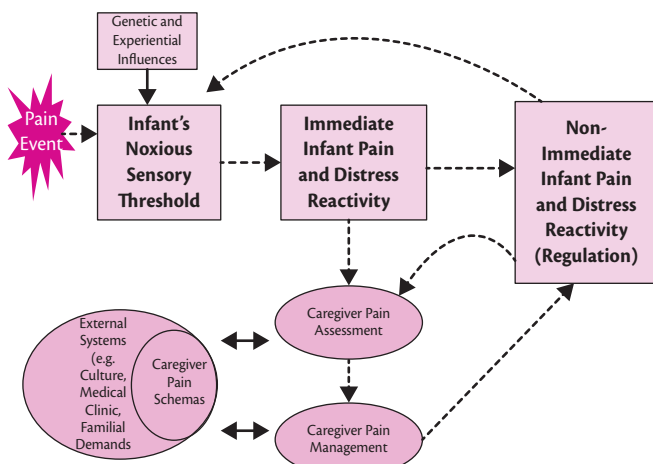

An appreciation of the unique developmental stage of infancy in terms of both the inter- and intrapersonal influences inspired the creation of a new biopsychosocial model specifically constructed to provide a framework for understanding acute pain over the first year of life: The 'development of infant acute pain responding' or DIAPR model (Pillai Riddell, 2009; see Figure 9.4). Acknowledging the SCM innovation of the primary role of the dynamics between caregiver and child, this new model incorporates novel components that have not been seen in other models of paediatric acute pain to date, including the separate conceptualization of the initial pain reaction and ongoing pain regulation, the *indirect* influence of larger social contexts, and the hypothesis of three specific feedback loops involving either the infant, the caregiver, or both. The model is based on evidence gathered from a growing literature base generated by the OUCH cohort (e.g. Ahola Kohut 2012; Pillai Riddell et al., 2011, 2013; Racine et al., 2012). The OUCH cohort is an ongoing cohort sequential sample of over 750 healthy children and parents being followed through routine immunization injections at 2, 4, 6, 12 months and/or most recently preschool age (with a subsample of 130 infants that was also followed at 12–18 months during a non-painful yet distressing parent–child interaction procedure).

The model begins with the chain of events arising from an acutely painful incident, typically conceptualized in terms of triggering biological processes related to a nociceptive threshold. The tissue stress

or damage is then transduced into an initial pain reaction via nociceptive afferents exceeding noxious sensory thresholds. Rather than pursuing the infinite challenge of operationalizing the non-verbal infant's subjective experience of the noxious stimulus, the model focuses on overtly measurable pain behaviours. After an immediate automatic/reflexive peak response is manifest following the painful event (observable via measures such as physiological or overt behavioural pain responses like cry, facial actions, or body movements), the infant begins the process of self-regulation towards re-establishing homeostasis (measurable via the decrease in overt pain responding as the immunization appointment progresses). Using complex, multifactorial modelling, emerging research on the OUCH cohort has clearly shown that the largest studied determinant of infant initial pain reactivity and pain regulation is the infant's earlier pain behaviour, either earlier in the specific immunization appointment or earlier in the life of the child.

Accordingly, over the first year of life in a standard immunization setting where almost all younger infants were immunized on an examining table and older infants were being held during immunization, specific caregiver factors (e.g. verbal reassurance, emotional availability, proximal soothing) have no to small relationships with infant pain behaviour, thus, the relegation of caregiver factors to peripheral determinant roles (compared to actual infant behaviour) in this infant-specific model. Moreover, all larger spheres of social influence, such as the family (e.g. the spouse or siblings), hospital ecology, or culture are speculated to exert influence *indirectly* through influencing the primary caregiver at the time the infant is in pain. For example, during an immunization, the parent's internal cognitive schema for pain will be influenced by cultural beliefs, availability/acceptability of pharmaceuticals, general pain knowledge and beliefs, skills for coping with the child's pain, and societal expectations for an infant's pain response. This schema in turn will influence caregiver pain assessment and management which then directly influences infant pain regulation and reactivity. Previous work confirming that a parent's recall of their child's painful immunization experiences was significantly determined by potential cultural stress (Pillai Riddell et al., 2007) add credence to this hypothesis regarding the influence of larger spheres on pain assessment.

There are three feedback loops inherent in the model. Consideration of the infant responding self-regulatory loop (see interrelationships between boxes in the model in Figure 9.4) suggests that within an appointment, the actual stimulus and the infant's sensory thresholds (influenced by previous pain experiences and genetic nociceptive thresholds) triggers an infant's initial pain reaction and that the initial pain reaction will contribute to determining regulation from the initial pain reaction. Moreover, it is postulated that future pain responding, through modification of pain thresholds, will be impacted upon by past pain responding (both initial pain reaction and the infant's regulation from it). Examination of the infant–caregiver regulatory feedback loop (see interrelationships *between* the boxes and the ovals in Figure 9.4) suggests that not only will a caregiver's initial assessment and management of an infant's acute pain be predicted by immediate pain reactivity, a feedback loop occurs relating to infant regulation and subsequent caregiver assessment and management. Thus, how an infant is regulating following the pain event will impact ongoing assessment and management in a cyclical fashion until the distress is no longer evident (i.e. infant regulation re-establishes homeostatic balance).

**Figure 9.4** The development of infant acute pain responding model (the DIAPR model).

Finally, unique consideration must be given to the broader psychosocial systems of infancy. A parent feedback loop (see relations between ovals in the model in Figure 9.4) acknowledges that while an infant's pain responding (i.e. initial reactivity and regulation) contributes to caregiver assessment and management of the infant's pain, information arising directly from the infant is accommodated within existing parental schemas of the situation, based on influences such as cultural norms, medical institution guidelines, and the familial demands.

Finally, to attempt to bring further awareness to the steep trajectory of development during infancy, in Figure 9.4 dashed lines were used to portray those relationships that are hypothesized to change in strength over the course of infancy. For example, simply comparing infants at 2 months versus 12 months, OUCH cohort research indicated that the influence of parental factors, such as sensitivity or verbal reassurance, on pain responding was stronger at 12 months of age than at 2 months of age. Moreover, the transition and relationships between pain responses (i.e. pain reactivity and pain regulation) changes according to developmental stages within infancy. Solid arrows suggest that while changes may occur over time, this is likely to be not as strongly linked to the infant's development. Thus, the model attempts to capture the interplay between and among infant and caregiver factors as they change over the first year of life.

While attempting to capture observable inter- and intrapersonal factors to generate specific testable hypotheses regarding the infant, the model does not yet specifically outlay specific caregiver schemas that may be filtering influences from larger spheres of culture, medical norms, etc. Understanding patterns regarding how these larger systems influence the parental schemas which in turn impact on their behaviour towards their child in pain is crucial in trying to target interventions.

### **Critical review of paediatric pain models to date and future directions**

Paediatric pain emerged as a distinct area of study in its own right relatively recently. There has been a proliferation of conceptual models over the past two decades. Generally speaking, these models share similar explanatory purposes in trying to understand the interplay among biological, psychological, and social processes during children's painful events. They postulate and emphasize different dimensions in seeking features of children's pain that are potentially modifiable to reduce pain and suffering in this vulnerable sector of society. Rather than conflicting with each other, the models reflect a remarkable degree of concordance concerning the key factors involved. However, one stark difference is the primacy of the caregiver. Most models embed the influence of the caregiver in a social dimension—only the SCM assigns caregivers a central role.

Interestingly, the biopsychosocial models presented here have chosen by design to either focus on acute or chronic pain. However, the formulations overlap. The models that examine the sequence of events involved in an acute pain episode acknowledge that previous pain experiences impact on current pain experiences. This provides an opportunity to examine relationships between acute and chronic pain. As Palermo and colleagues' models of chronic pain (2005, 2012) suggest, very similar aspects of the biology, psychology, and social environment (such as physical health, coping mechanisms, and culture) come into play, yet no models to date have attempted

to explicitly bridge the theoretical gap that currently separates acute and chronic pain. The opportunity may be available in the study of biopsychosocial factors that are involved with the transition from acute to chronic pain. In children this must give consideration to the developing nervous system.

A problematic tendency of most paediatric models has been to treat pain expression as a unitary construct. Yet, as others have acknowledged in the more adult-centric theoretical literature (e.g. Hadjistavropoulos et al. 2011), there are both automatic-reflexive components and more controlled-cognitively mediated components to pain, with both reflecting ontogenetic and socialization features of pain experience and expression. Pragmatically, one also could acknowledge this divide using a similar dichotomy based on pain reactivity (a child's immediate response to a painful event) versus pain regulation (a child's pain and distress temporally distal to the actual painful event as the child moves toward re-establishing homeostasis). It would follow that the strength of impact of biopsychosocial factors would vary, with more innate/reflexive factors (e.g. pain receptor density, temperament) likely more prominent with pain reactivity and psychosocial factors (such as attachment, cultural beliefs about the value of pain, gender biases) likely more important determinants of how the child self-regulates subsequent to the painful event.

The most important limitation of existing biopsychosocial models of paediatric pain arises from how development is handled. With a few focused exceptions, we know little about the developmental transformations in biological, psychological, and social bases of pain through infancy, childhood, and adolescence, particularly through longitudinal study. While all existing models acknowledge the importance of development, it is argued here that in biopsychosocial models the interplay of these dimensions must be recognized as different across childhood (defined here as from birth to adolescence).

Taken from the larger field of child development, Arnold Sameroff's unified theory of development (2010) provides an exemplar for this position. At the core of this model is the tenet that while biological, psychological, and social factors are important in understanding all stages of the developing child, the magnitude of influence varies through infancy, childhood, adolescence, and adulthood. Factors external to the child increase in prominence with age and exposure to ecological systems, such as those provided by parents, the family, peers, and the community (including health care system and geopolitical contexts). One can then discern that to the newborn infant larger psychosocial contexts (culture, community norms, institutional practices, etc.) outside the self are not directly consequential (they likely indirectly impact on the infant through a caregiver's mediation of these factors). These influences change over time as attachment bonds are formed with primary caregivers over early infancy and childhood and then as the child enters into new systems of psychosocial influence such as daycare, elementary, or university spheres.

Although challenging, given the crucial nature that developmental stage plays in paediatric pain, it is imperative that this role is acknowledged more specifically because the relative weight of related factors change over time. One alternative would be to create models specific to unique stages of life as in the DIAPR model. Biopsychosocial models could then be more explicit and clearly elaborate on key factors involved within the specified age range, without fear of becoming convoluted. Potential developmental 'phases', based on key

### Case example

Leah is 4 years old and her parents would describe her as being 'sensitive' to tactile and noxious stimulation. She is about to have her preschool immunization. Her mother and 1-year-old brother are waiting with her in the examination room. She told her mother earlier that she did not want to go to the doctor today because she hates needles. Her mother reminded her to behave because 'good girls don't make a fuss'. Her mother also reminded her that when she was a young girl her mother gave her a spanking if she embarrassed the family by overreacting in public. Adding to her dismay about the appointment, Leah had to miss her favourite period in junior kindergarten, music, to come to the doctor. The minute the doctor entered the room Leah started crying, which triggered her younger brother's tears. Her mother soothed her young son and apologized to the doctor for Leah's outburst. By the time the doctor could restrain Leah and quickly insert the immunization needle, Leah expressed maximal pain behaviours and took a long time to calm down after the needle.

Acute immunization pain is just one type of pain that children face over the span of childhood. As Leah's case helps illustrate, to best understand her pain experience and responding, one must take a biopsychosocial perspective.

areas of development (e.g. reliance on parents versus peers, ability to self-report, biological/physical changes), could be birth through infancy (0–2 years), early childhood (3–6 years), middle childhood (7–12 years), and adolescence (13–18 years). This would allow for models that more precisely outline the relative contributions of features and roles of biology, psychology and the social environment.

### Conclusion

A child's experience of pain is an important area of focus within the broader pursuit of understanding human suffering. Developing biological and psychological capacities and social interactions distinguish infant, children, and adolescent experiences from those of the mature adult. The social contexts of pain, which interact with the child's biological and psychological action tendencies, are defined strongly by the impact of direct caregivers such as parents. Existing models in the field primarily describes these relationships separately for acute and chronic pain—integration is necessary. Future models could benefit by careful consideration of developmental stage factors.

### Key recommendations

Having reviewed current biopsychosocial models of paediatric pain, key recommendations stemming from this work can be made:

- (1) Biological, psychological, and social dimensions are useful constructs that encapsulate the key factors influencing paediatric pain.
- (2) These dimensional influences are not static, but rather are dynamic, not only over the child's development, but also over the course of a discrete painful event or episode.
- (3) More work that acknowledges how factors within a dimension impact on the child differentially over different developmental stages will prove theoretically and pragmatically beneficial.

## CHAPTER 10

# Cognitive styles and processes in paediatric pain

Liesbet Goubert and Laura E. Simons

### Summary

Chronic pain is prevalent in children and adolescents. The current chapter outlines an interpersonal perspective on child pain, demonstrating the central role of child and parent pain-related cognitions in the development and maintenance of chronic pain in childhood. Pain takes place within a social context: children's expressions of pain (e.g. facial pain displays) are observed and decoded by others (parents), eliciting emotional and behavioural responses. Parents' responses may impact child outcomes in two ways, directly by imposing activity limitations/encouraging activity engagement or indirectly through observational learning. Although personality and temperamental factors may predispose children and parents to perceive pain as more or less threatening to deal with, the model presented in this chapter focuses on proximal pain-related cognitive processes and associated behaviours that contribute to pain-related disability in children. Recent evidence suggests that perceptions of pain as highly threatening (i.e. catastrophizing) may lead to fearful reactions to pain, activity avoidant behaviours, and more disability. In parents, catastrophizing thoughts about child pain are associated with higher levels of child disability, with recent evidence implicating parent protective behaviours as a mediating mechanism.

### Introduction

Chronic and recurrent pain is prevalent in children and adolescents, with median prevalence rates ranging from 11% to 38% (King et al., 2011). A study in 987 children recruited from the general population showed that one-third of children and adolescents who were experiencing chronic pain at baseline reported chronic pain at 1-year and 2-year follow-up (Perquin et al., 2003). Most children seem to function well despite pain, although a minority (5%) are moderately or severely disabled across several domains of functioning (Huguet and Miro, 2008). The central question is why some children easily recover from pain and resume daily activities, while others seem to experience it as a major burden, hindering them in pursuing daily activities. This chapter will outline an interpersonal perspective on the development and maintenance of child chronic pain complaints, describing the role of cognitive processes in children and parents. Additionally, challenges for future research will be discussed.

### Setting the stage: personality and temperament

Since the introduction of the gate control theory of pain, it has been increasingly acknowledged that the way individuals perceive and interpret pain is a determinant of pain outcomes. Early studies demonstrated that people's personality or characteristic ways of thinking impact how they process pain. Most studies focused upon the role of neuroticism—i.e. the trait-like tendency to experience a broad range of negative feelings such as distress or worry—which has been associated with a heightened experience of bodily sensations (Watson and Pennebaker, 1989), and, in particular, pain (Charles et al., 2008). In the context of paediatric pain, a fearful temperament has been identified as a predictor of somatic complaints 1 year later (Wolff et al., 2010) and 7 years later (Rocha and Prkachin, 2007). Furthermore, adolescents suffering from chronic pain have been found to be more vulnerable than healthy peers in terms of neuroticism (Merlijn et al., 2003). Originating from the positive psychology movement, the concept of optimism—i.e. the generalized expectancy of positive outcomes—has received increasing attention in the context of pain. In particular, optimism has been linked with lower pain reports in adults (Geers et al., 2008) and adolescents (Mannix et al., 2009; Williams et al., 2010). In children with cancer, Williams et al. (2010) demonstrated that optimism primarily related to lower self-report of pain and better emotional functioning, while pessimism was linked to poorer mental health.

Although these studies indicate that temperament and personality traits have a direct effect upon pain outcomes, other research has suggested that personality variables are better viewed as vulnerability or resilience factors, impacting on pain outcomes through more proximal variables involving pain-specific cognitive processes (Goubert et al., 2004; Hood et al., 2012; Leeuw et al., 2007; Muris et al., 2007; Vervoort et al., 2006).

### Pain-specific cognitive processes

A cognitive process which has received ample attention in the pain literature is catastrophic thinking about pain, characterized by an individual's tendency to focus on, and exaggerate, the threat value of painful stimuli and negatively evaluate one's own ability to deal

with pain (Sullivan et al., 2001). Extensive evidence is available that catastrophizing about pain relates to more intense pain and higher disability (Leeuw et al., 2007), and also is predictive of the persistence of pain and disability (e.g. Linton et al., 2000). Catastrophic thinking has been shown to give rise to an excessive fear of pain/injury (Goubert et al., 2004), which, in turn motivates individuals to escape or avoid activities thought to induce pain. Numerous studies have shown that catastrophizing thoughts about pain and pain-related fear (i.e. fear-avoidance beliefs) exert their effects upon pain experience and pain-related disability through longstanding avoidance behaviours and physical inactivity (Leeuw et al., 2007).

In line with the vulnerability hypothesis, several studies have demonstrated that neuroticism impacts on pain outcomes through catastrophizing about pain, in adults (Goubert et al., 2004) and children (Vervoort et al., 2006). Furthermore, a study in young adolescents showed that reactive temperament traits (involving fear and anger-frustration) were positively associated with pain catastrophizing, whereas regulative traits (i.e. attention and inhibitory control) were negatively associated with catastrophizing about pain (Muris et al., 2007). Interestingly, a recent study in healthy adults demonstrated that the protective link between optimism and pain perception operates through lower catastrophizing thoughts about pain, suggesting that individuals who are lower in optimism are more likely to ruminate, magnify or feel helpless about their pain experience, resulting in higher pain (Hood et al., 2012). Given the bulk of evidence supporting the proximal link of pain-specific cognitive processes on outcomes, the remainder of the chapter will primarily focus upon the role of fear-avoidance beliefs in children and parents.

### **Fear-avoidance beliefs in children: catastrophizing and pain-related fear**

In recent years research has accumulated demonstrating the importance of fear-avoidance beliefs in the context of paediatric pain. Although the available evidence is markedly smaller than in adults, the findings are consistent with the adult literature. Child pain catastrophizing has been found to be related to higher pain intensity in samples of healthy school children and children with chronic pain (e.g. Hermann et al., 2007) and to lower pain tolerance (Piira et al., 2002). High catastrophizing children with chronic pain also report having more difficulty performing daily activities in home, school, recreational and social domains (Crombez et al., 2003; Guite et al., 2011). To our knowledge, only one prospective study of pain catastrophizing is available in children (Vervoort et al., 2010), indicating that it contributes to increased pain and disability 6 months later.

Research examining the theorized consequent of pain catastrophizing, pain-related fear, has gained support in relation to pain-related outcomes. In a small pilot study, Martin and colleagues (2007) found that pain-related fear accounted for 40% of the variance in pain-related disability. In another study, child pain-related fear predicted physical activity limitations beyond the influence of pain and depressive symptoms (Wilson et al., 2011). Furthermore, in a recent study among paediatric patients experiencing acute post-surgical pain, pain-related fear was associated with pain unpleasantness and functional disability 2 weeks after surgery (Page et al., 2011). In paediatric patients with persistent pain, Simons et al. (2011) found higher levels of pain-related fear to be associated with more frequent physician visits and higher levels of functional disability. In addition, a decrease in pain-related fear over a 1-month period

was associated with a decrease in functional disability, suggesting that a decline in pain-related fear corresponds with a resumption of daily activities. This study also examined the relationship between pain catastrophizing and pain-related fear. As expected, these sequentially linked variables were highly related to one another. At present, no studies have examined the sequential predictive role of pain catastrophizing to pain-related fear to pain-related outcomes in children. Proceeding from a cognitive-behavioural model of pain (see Leeuw et al., 2007), pain-related fear and escape or avoidance behaviours are expected to mediate the association between catastrophizing and the chronification of pain.

### **Children's fear-avoidance beliefs in a social context**

It has become increasingly clear that child pain does not exist in a social vacuum. The biopsychosocial model of pain communication of Hadjistavropoulos and colleagues (2011) outlines how pain becomes a social experience. Following a pain stimulus, a child encodes its internal experience of pain into an expressive display of pain (e.g. facial pain behaviour), observable to others (e.g. parents). These expressive displays demand attention from others, which are then decoded (i.e. discriminated and interpreted), and may elicit emotional (e.g. distress) and behavioural responses (e.g. comforting) in the parent (Goubert et al., 2005). In turn, parents' responses may impact the child's experience and expression of pain. A comprehensive understanding of pain as a *social* experience (i.e. the dynamic interplay between a child's pain experience and the social environment in which pain emerges) thus requires consideration of expressive (i.e. how is pain communicated to others) and receptive features (i.e. how is pain perceived by others) of pain (Hadjistavropoulos et al., 2011).

On the expressive side, studies have indicated that children are able to modulate their expression of pain. An important determinant of pain expression is the intensity of pain experienced. Yet, pain intensity only explains a small to moderate amount of the variance in children's pain expression (Vervoort et al., 2009). A child's display of pain may vary according to the way a child is socialized to think and behave when in pain. Studies have shown that children's expression of pain depends on the beliefs endorsed about pain and the child's perceived ability to cope with it. Specifically, in line with research in adults (e.g. Keefe et al., 2003), recent findings revealed that children who endorse high levels of catastrophizing about pain express high levels of pain, regardless of the intensity of pain experienced (Vervoort et al., 2009). Furthermore, contextual factors, such as the presence of others, may be critical in understanding varying levels of child pain expression (Hadjistavropoulos et al., 2011). Children may consider the potential response from the other when deciding to express or hide pain. For example, children as young as 9 years old report being less likely to express pain in front of a peer than in presence of their parent because they expect more negative reactions from peers compared to parents following pain disclosure (Zeman and Garber, 1996). Furthermore, the social context may interact with children's beliefs in the impact upon child's pain expression. Of interest in this regard are studies from Vervoort et al. (2008, 2011a), investigating the impact of different types of observers in the relationship between child pain catastrophizing and child's display of pain. An interesting finding from these studies is that children who perceive the pain as threatening (i.e. catastrophize) indiscriminately

display their pain, regardless whether they are alone, with a stranger, or with a parent. In contrast, low-catastrophizing children modulated their expression depending on whether a solicitous response is more likely (e.g. higher expression in presence of parent compared with when alone or in presence of a stranger).

Yet, it is still largely unknown why children who catastrophize express more pain, and the impact upon others. The findings of Vervoort et al. (2008, 2011a) support the suggestion of Sullivan et al. (2001), that catastrophizing about pain has an interpersonal function. In particular, it has been suggested that, through a heightened display of distress, individuals who catastrophize may be maximizing the probability that potential caregivers will maintain proximity or offer support or assistance (Sullivan et al., 2001). To truly understand the dynamics of children's pain catastrophizing in a social context, understanding the nature of the interaction between the child in pain and those able to provide care is essential. It is still unclear what type of responses high catastrophizing children elicit in others and how, in turn, these responses influence the child's future pain experience. Research in adult populations has indicated that others' responses toward high catastrophizers can vary substantially; catastrophizing appears to elicit positive responses such as the provision of instrumental support as well as negative responses such as criticizing the sufferer in pain or responding punitively (Keefe et al., 2003). In the context of paediatric pain, a recent study suggests that child catastrophizing may not always elicit solicitous responses, but also discouraging responses (e.g. criticism), although this association was only found for mothers (Vervoort et al., 2011b). This study also indicated that the negative effects of child catastrophizing upon pain outcomes may be reduced when parents promote well behaviours in their child. Only one pilot study could be found that has examined the relationship between child pain-related fears and parent responses to pain. Wilson et al. (2011) found that child pain-related fear and parent protective responses to pain were significantly correlated, with child pain-related fear mediating the relationship between protective parent responses and child activity limitations.

In sum, the available evidence suggests that observing their child in pain may initially elicit positive attention or care in parents. Over time, however, repeated exposure to their catastrophizing child's pain complaints may become a source of frustration and distress. In addition, the way in which high-catastrophizing children communicate their distress and demand help may impact parent responses. Lastly, differences found between mothers and fathers underscore the importance of examining each parent, rather than restricting our understanding of this complex phenomena to only mothers (Hechler et al., 2011). Clearly more research is needed in this burgeoning area of inquiry.

## Fear-avoidance beliefs in parents

Beyond investigating the type of responses pain catastrophizing in children elicits in others and how these responses impact upon the child's future pain experience, it is also important to investigate who is likely to be less or more sensitive and responsive to heightened pain displays in the child (i.e. the receptive side) (Goubert et al., 2005; Hadjistavropoulos et al., 2011). Not only characteristics of the child, such as the extent to which the child engages in pain expression, but also characteristics of the observer and contextual variations are important here. These different influences are clearly described within a recent model of empathy and pain (Goubert

et al., 2005, 2009, 2013). When a child displays an internal experience of pain, others attend to, discriminate, and interpret pain signals, which may give rise to emotional (e.g. distress) and behavioural responses (e.g. comforting), with strongest reactions elicited by more intense pain displays. Yet, child pain expression is not the only source of information for others. Both characteristics of the observer (such as beliefs about the pain) and characteristics of the context may be important here.

In line with the cognitive-affective model of pain (Leeuw et al., 2007), it is likely that parents who perceive their child's pain as highly threatening (i.e. have catastrophic thoughts) may experience high distress, and, accordingly, feel motivated to engage in behaviours aimed at the reduction or avoidance of pain in their child, at the expense of other important domains (e.g. school performance) in the child's life. For example, it is reasonable to assume that parents, who perceive the child's pain as highly threatening and dangerous, may keep their child home from school more frequently. Preliminary evidence is available. Studies have shown that more protective behaviours from parents are associated with higher child disability (Peterson and Palermo, 2004; Simons et al., 2008). Furthermore, it was found that higher parental catastrophizing about their child's pain is related to higher parental distress (Caes et al., 2011; Goubert et al., 2006), higher child disability and lower school attendance (Goubert et al., 2006), and a higher tendency to restrict their child's pain-inducing activity (Caes et al., 2011). When examining parent catastrophizing and protective parent behaviours together, protective behaviours mediated the relationship between parent catastrophizing and child school functioning (Logan et al., 2012) and partially mediated the relationship between catastrophizing and functional disability (Sieberg et al., 2011). Additionally, parent pain-related fears are related to higher levels of child functional disability and child healthcare utilization (Simons et al., 2011). More insight into these mechanisms is expected to be of crucial clinical significance, as it will enable us to identify those parents who negatively influence children's vulnerability to deal with pain, and, as such, increase children's risk for delays in academic or social skills due to persistent pain problems.

One might argue that some level of parental worry is necessary as children depend upon parental care and protection. In this context, it might be useful to redefine catastrophizing as (more) extreme levels of parental worry. Indeed, very low levels of parental worry may fail to elicit parental care. Very high levels of parental worry, on the other hand, may relate to 'catastrophizing', with its maladaptive consequences for child outcomes. Future research may disentangle which levels of worry are most adaptive with the possibility that moderate levels of parental worry are most adaptive and promote effective child self-regulation of distress, while at the same time facilitating empathic concern and attention for the needs of the child (Caes et al., 2011).

Parental beliefs about pain and parental behaviours may not only influence children's pain and disability in a direct way, but may also have an indirect impact by means of observational learning processes. Observational learning has been defined as changes in patterns of behaviour that are a consequence of observing the behaviour of others (Goubert et al., 2011). In the context of pain, a child may acquire information about a particular situation and about the consequences of specific actions in that situation through observation of another's behaviour (e.g. parent) in that particular situation. For example, children who observe their parents displaying fear and avoidance reactions to back-stressing activities, such as lifting heavy

objects, may adjust their appreciation of that particular situation ('back-stressing activities are dangerous') and the behavioural consequences ('avoidance of back-stressing activities reduces pain'). This information may translate into changes in attitudes and behaviour immediately, e.g. acquisition of catastrophizing thoughts related to certain activities, or later when the child experiences pain him/herself. In this way, how parents perceive pain and cope with pain may impact children's beliefs and behavioural repertoire (Goubert et al., 2011). Although early studies have found evidence for social modelling effects, indicating that observational learning influences both observable expression of pain as well as subjective experience (Craig, 1986), the evidence in the context of paediatric pain is limited. Few available studies suggest that families may influence children's experiences of pain through family members' own experiences/history of pain and use of coping strategies in dealing with their own pain and their child's pain (e.g. Thastum et al., 1997). To our knowledge, only one experimental study in children and their mothers showed that children displayed lower pain thresholds for a cold water task when their mother had voluntarily exaggerated her pain (Goodman and McGrath, 2003). Further research is needed to investigate the role of observational learning processes in the development of catastrophizing thoughts and pain-related fear in children.

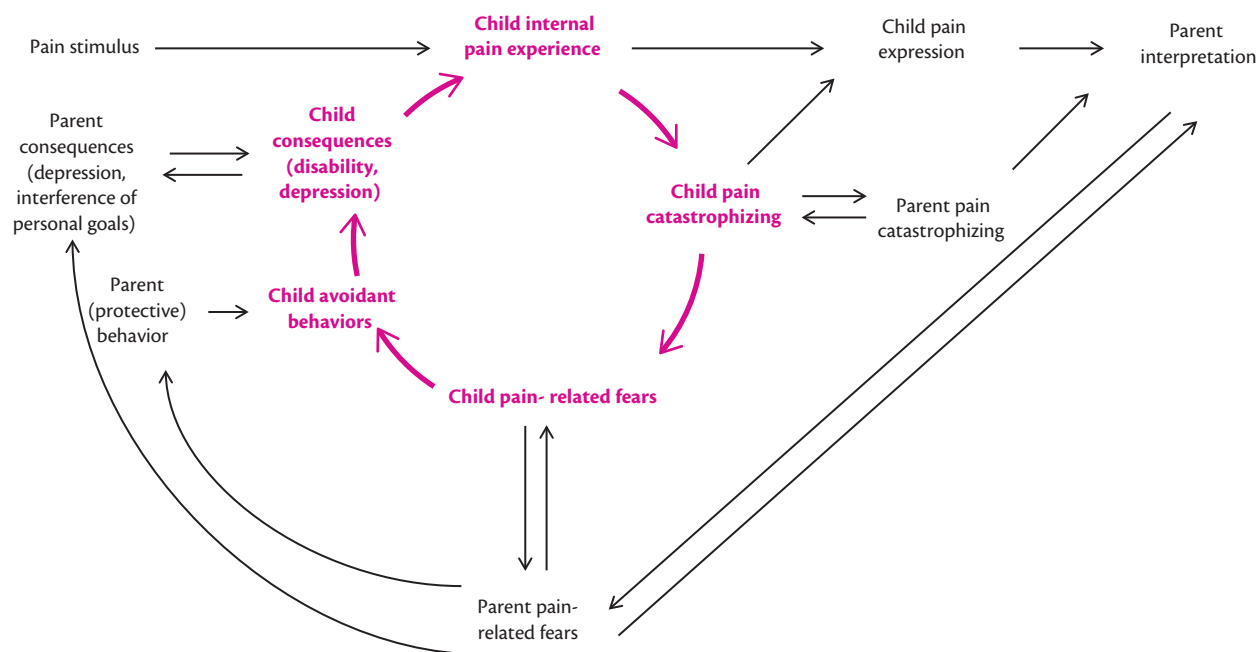

### Interpersonal fear avoidance model of pain

Based upon current evidence, the present chapter proposes a model involving pain-specific cognitive processes to understand how acute paediatric pain may evolve into chronic problems. Recent evidence suggests that a key determinant of adverse child outcomes may be a child's prioritized focus upon pain relief resulting in avoidance of daily activities (e.g. school, hobbies), motivated by fearful and catastrophic thoughts about pain. Prolonged avoidance of daily activities may result in long-term disability, child depression, and even delays

in the normal child's development. Indeed, prioritized pursuit of pain control goals may hinder the pursuit of developmentally appropriate goals, such as the achievement of new academic and social skills. Children who endorse high levels of worrisome thoughts about pain (i.e. catastrophize) may be likely to become entrapped into a vicious cycle of pain, fear, and prolonged disability (see Figure 10.1).

Child pain, however, takes place in a social context, of which parents are most influential agents. On the expressive side, a child encodes its internal experience in an overt display of pain, with high catastrophizing children engaging in an indiscriminate display of pain. On the receptive side, a parent decodes the child's pain signals, which may give rise to their own emotional and behavioural responses. Parents' catastrophizing thoughts about their child's pain may impact the decoding of the child's pain, fuelling pain-related fears, and motivating toward (over)protective behaviours. These parental responses, may, in turn, impact the child's pain-related cognitions, fears, and behaviour, and may promote child disability. Furthermore, when the child's pain becomes chronic, parents may become continuously focused upon the goal of alleviating their child's pain, which might interfere with other personal goals they have (e.g. work performance). This may lead to frustration, feelings of incompetence, and eventually depressive feelings in parents, which might, in turn, impact the child (see Figure 10.1).

As mentioned previously, more research is needed to understand the differential influence of mothers and fathers. In some cases, fathers may counteract the impact of mothers, who have generally been found to ruminate more about their child's pain than fathers (Hechler et al., 2011). For example, while both mothers and fathers with high levels of catastrophizing have been found to report a stronger inclination to engage in solicitous behaviours, only catastrophizing fathers also reported a stronger tendency to engage in behaviours discouraging child's pain expression or distracting child's attention from pain (Goubert et al., 2012; Hechler et al.,

**Figure 10.1** Interpersonal Fear Avoidance Model of Pain.

2011). Furthermore, given the impact of both child and parent variables in determining child outcomes, it is reasonable to assume that child and parent catastrophizing may have a cumulative impact; i.e. children who catastrophize about pain, and have pain-related fears, whose parents also have catastrophic thoughts about child pain might be at highest risk for longstanding problems.

Finally, contextual variables may modulate child and parent responses. A pertinent contextual variable may be the situational threat value of pain. For example, pain of unknown origin (i.e. functional pain) may be particularly threatening for parents (Williams et al., 2009), motivating parents (especially, those who already have catastrophizing thoughts about their child's pain) to engage in protective behaviours (Goubert et al., 2012). Furthermore, information a family receives regarding pain and its management (e.g. by a physician) may impact how child and parent cope with it. Research examining the role of contextual variables beyond child and parent pain-related cognitions/fears is an emerging and important area of inquiry.

## Clinical implications

Extensive evidence points to the usefulness of cognitive-behavioural interventions in targeting catastrophic thoughts and pain-related fears in adults (Smeets et al., 2006). In children and adolescents, cognitive-behavioural approaches are also gaining support (Eccleston et al., 2002; Logan and Simons, 2010). Further research is needed to examine whether targeting catastrophic thoughts in parents is an efficient way to promote better pain outcomes in children. Furthermore, when families become trapped in a vicious cycle of pain, catastrophizing, fears, and disability, and the pain problem dominates family life at the cost of other important life goals, acceptance-based therapies may help families to give up the dominant search for a definitive cure for pain and reorient their attention toward positive everyday activities and other rewarding aspects of life (McCracken and Eccleston, 2003). Although most research on acceptance-based strategies has taken place in the context of adult pain (Veehof et al., 2011), two treatment studies among adolescents using an approach combining exposure and acceptance-based strategies support its effectiveness in adolescents (Wicksell et al., 2007, 2009). These studies found that pain-related fear, in addition to pain and disability, reduces following treatment.

To prevent the initiation of a vicious interpersonal cycle of fear-avoidance beliefs and the development of chronic pain problems, screening for vulnerability factors, such as high neuroticism may be useful. However, it has been suggested that individuals with an increased vulnerability may be less changeable in their fear-avoidance beliefs compared with individuals without pre-existing vulnerabilities (Leeuw et al., 2007).

Finally, further research is needed regarding variables that buffer against the development of catastrophizing thoughts and pain-related fear (e.g. optimism). Given that optimism may foster confidence to overcome stressful situations (Hood et al., 2012), interventions promoting positive optimistic beliefs in children and parents may have potential in the prevention or recovery from chronic pain problems.

## Conclusion and future challenges

In this chapter, we outlined how child and parental cognitive styles and processes may impact the development and the maintenance of chronic pain complaints. Child and parent beliefs about pain

and pain-related behaviours interact in determining child pain outcomes, with trait-like cognitive styles (e.g. neuroticism, optimism) acting as a vulnerability or resilience factor to developing catastrophic thoughts about pain and pain-related fears. Our understanding of childhood pain/disability may further benefit by focusing in future research on the motivational context of child and parent fear-avoidant behaviours. When pain persists, pain control may become the most dominant goal for children and parents who engage in catastrophic and fearful cognitions at the expense of other valuable life goals, resulting in persistent disability and/or depression (see Crombez et al., 2012). Child and parent may become frustrated because of experienced conflicts between pain-related goals (i.e. goals related to the reduction of pain) and other (e.g. social, academic/work) goals, potentially resulting in feelings of incompetence, and eventually depressive feelings. When attempts to solve the pain problem have repeatedly failed, adequate functioning and the successful attainment of developmental goals may depend upon the adjustment of unattainable goals (e.g. no exclusive focus on pain elimination) and the engagement in new goals (e.g. learning to function despite pain) by both child and parent. Evidence is accumulating that the ability to disengage from and adjust unattainable goals is positively associated with quality of life (Crombez et al., 2012). Future study is warranted regarding the goals parents and children pursue when faced with child pain, the concordance in the goals parent and child value, and the effect upon a child's functioning.

### Case example

Molly is an athletic 13-year-old girl who suffered a hyperextension injury to her non-dominant left wrist when she fell backward trying to head a ball while playing in a soccer tournament. Working under the presumed diagnosis of a fracture, Molly underwent a series of castings, splints, and physical therapy. Notably, Molly reported intense pain throughout. Several months after her initial injury, she was diagnosed with complex regional pain syndrome, type II and underwent a left supraclavicular brachial plexus block and left ulnar nerve block. She reported only transient relief with this treatment. Shortly after the block Molly was evaluated in a multidisciplinary pain clinic by a physician, physical therapist, and clinical psychologist.

Molly and her mother presented for the evaluation in significant distress. Molly's mother indicated that in the past 6 months Molly's symptoms had only worsened and stated that 'something had to be done immediately' to help her daughter. Throughout the evaluation, Molly's mother would often quickly respond to questions directed at Molly. At the time of evaluation Molly described her pain as 7 to 8/10 in her left wrist and forearm. She described burning, sharp shooting, and throbbing pain from her fingers to her left shoulder. She also described pins and needles, weakness, and muscle twitching. She reported increased pain with activity and at rest. She described associated colour changes of her left hand and wrist to blue and purple, as well as increased oedema, sweating, and hair growth. Molly had significantly limited her involvement in sports, no longer participating in basketball or lacrosse (her favourite sport). She continued to play soccer, with a splint on the left wrist. Molly missed several days of school due to pain and her sleep was significantly disrupted. With regards to social history, Molly lives at home with her mother, father, and three younger

siblings (brother aged 12, sister 10, sister 7). Prior to her injury, it was expected that Molly would regularly help to care for her three younger siblings. Her father is in sales and mother is a stay-at-home mom, who played lacrosse in college and coaches Molly's lacrosse team. Recommendations at the evaluation included continued medication management of gabapentin Neurontin, three times weekly physical therapy, and initiation of biofeedback/relaxation training.

For the next 9 months, Molly struggled with her pain symptoms with multiple follow-up medical appointments, medical tests, and three subsequent sympathetic blocks. She attended limited sessions of biofeedback training. Notably, Molly and her mother presented very distressed at appointments and expressed significant frustration that her pain did not seem to be resolving. Without physician direction, Molly's mother weaned her from all medications. Molly did experience periods of improved functioning during a spring vacation to Florida and multiple weeks in the summer while vacationing at the family's summer home.

After a period of improved symptoms, Molly experienced a flare in her symptoms approximately 18 months after her initial injury, shortly before the start of the lacrosse season. Molly presented frustrated and sad. Her sleep was significantly disrupted and she was arriving to school late or missing the day entirely most days. She had almost completely stopped using her left arm and complained of intense, constant pain. After re-evaluation at the pain clinic, she underwent an additional sympathetic block and re-initiated psychological treatment. In addition to a focus on biofeedback and relaxation training, Molly set goals to: (1) attend a full week of school, (2) play in a soccer game, (3) deal with her frustration better with family members, (4) spend more time with friends, and (5) improve her mood. Molly was introduced to 'radical acceptance' of her pain symptoms versus the internal struggle with her pain in an effort to diffuse some of the anger and frustration that she had towards her pain and increase her ability to tolerate her physical discomfort. Molly also explored her values in each domain of her life and noted how little pain had to do with her valued life directions. The patient was able to eloquently describe the difference between 'acceptance' and 'giving up.' She talked about living a meaningful and enjoyable life regardless of the presence of pain. Although the pressure of performing in lacrosse was discussed and explored, Molly denied that this played any role in her symptoms. In collaboration with Molly's mother, Molly began attending school full-time again. This initially increased Molly's pain and frustration and Molly's mother struggled to tolerate her daughter's distress, leading her to question the treatment plan. Through multiple family meetings with Molly and her mother centred on re-emphasizing Molly's valued life directions, treatment alliance was re-strengthened and Molly continued to make gain in her functioning. At the conclusion of psychological treatment, Molly was able to increase the frequency and intensity of her physical therapy treatment and she was playing soccer (scoring the winning goal for her team at a recent game).

## CHAPTER 11

# Pain in cultural and communicative contexts

Ignasi Clemente

### Summary

Pain and culture are complex and multifactorial phenomena. They defy objectification, isolation, and simplification. They can neither be defined nor measured easily, since they intersect with the biological, psychological, and social realms. Taking into account the intrinsic multidimensionality of each phenomenon, we are only beginning to understand the myriad of ways in which culture may influence pain. As a consequence, (1) the study of the relationship between culture and pain is fraught with methodological and theoretical challenges; and (2) there is no conclusive evidence to support specific guidelines on how to assess and treat pain of specific cultural groups.

Pain in children is too often underestimated and undermanaged (Craig and Riddell, 2003). The situation is worse for cultural–racial–ethnic minority children, who are marginalized, relegated to the lowest socioeconomic status, and with multiple barriers that reduce or block their access to health care. The significant health disparities that minority children experience aggravate ever further their vulnerability (Kristjansdottir et al., 2012): their pain is persistently underassessed and undertreated.

Evidence emerging from multiple methodological approaches reveals that cultural factors may influence specific aspects of pain experiences more than others. While it is unclear how the sensory aspects of pain may be affected by culture, the evidence illustrates how culture affects pain response, even at an early stage in an infant's life.

In addition to cultural factors across different settings, pain experiences are also affected by the communicative factors specific to a particular environment or situation in which pain responses, self-report assessments, and descriptions occur. Pain is highly susceptible to its immediate communicative environment in subtle ways. Clinicians need to become aware of their own cultural biases, assumptions, and beliefs. A place to start is to observe and talk to the paediatric patient and his/her family.

I begin the chapter by defining three key concepts (culture, ethnicity, and race), and by presenting the methodological and theoretical problems of the research on pain and culture. The chapter proceeds with an examination of the evidence on the relationship between paediatric pain and culture, organized by the methodology

used (experimental, interview, self-report, and observational). The examination of paediatric pain in cultural context is followed by a synoptic description of the sociomedical and socioeconomic contexts of paediatric pain, with a focus on professional cultures and health disparities. The chapter closes with a discussion of the communicative, environmental, or situational factors that impact children's acute and chronic pain experiences.

### Introduction

Over the last 50 years we have learned that pain is a multidimensional, complex, and subjective (sensory and emotional) experience (Charlton, 2005; Merskey and Bogduk, 1994). Cultural and communicative factors are consistently acknowledged by pain research, yet elusively studied, perhaps because of the inherent complexity of the two phenomena.

### Key concepts: culture, race, and ethnicity

Culture, often confused with the terms 'ethnicity' and 'race' (Edwards et al., 2001; Finley et al., 2009; Kagawa-Singer, 2001), is as complex and multifactorial as pain. Culture is 'an ethereal concept with a multitude of definitions' (Bernstein and Patcher, 2003, p. 142). Defining culture, ethnicity, and race is challenging. Operationalizing them is even more difficult, since these categories cannot be isolated and formulated into discrete independent variables (Clay, 2009; Craig and Pillai Riddell, 2003). They influence and are influenced by gender, age, and socioeconomic class to name a few. Furthermore, they are dynamic, socially and historically changing phenomena. Culture, ethnicity, and race are no different than definitions of pain and childhood, which have also changed historically (Bonica and Loeser, 2001; Edwards et al., 2001; James and James, 2004; Unruh, 1992).

Culture is 'the collection of malleable, adaptive strategies that groups of people have developed to survive in their ecologic niche' (Kagawa-Singer, 2001, p. 228). Culture is: (1) *adaptive*, dynamically ever-changing to meet social and environmental changes; and (2) *heterogeneous*: cultural groups have internal or intracultural variation in terms of socioeconomic class, gender, age, education, rural/urban setting, religion, and so forth. Such significant internal variation can be found throughout this chapter, for instance,

regarding the differences within the label of the 'Asian' child between Japanese, Chinese, Isan Thai, central and southern Thai, and southern Taiwanese. Rigid and deterministic definitions of culture found in health and social policy research often ignore individuals' ability to act and change, as well as obscure similarities and emphasize differences between cultural groups (Ahmad, 1996).

Race is an ideological construct that has been associated with colonialism, inequality, and the imposition of a hierarchy of dominant people over dominated others. Race as a scientific category is a myth (Kagawa-Singer, 2001). The American Anthropological Association (1998) and the American Association of Physical Anthropology (1996) underscore that 'race' is not a scientific category based on clearly demarcated and consistently distinct 'racial' biological groupings. Phenotypic differences, for instance, differences in skin colour, do not match genetic differences (Craig and Pillai Riddell, 2003; Kagawa-Singer, 2001). Most genetic variation (94% of the human DNA) lies within the so-called racial groups, whereas only 6% occurs between racial groups (American Anthropological Association, 1998).

Ethnicity simply denotes differences between two groups. Ethnicity is not culture, since culture refers to ways of doing, thinking, feeling, and being. Unlike essentialist 'racial' differences based on purportedly biological differences, ethnic differences depend on nationality, tribe, religion, language, culture, history, experience, ancestry, and beliefs (Craig and Pillai Riddell, 2003; Edwards et al., 2001; Kagawa-Singer, 2001). The term ethnicity is misused when: (1) some kind of ethnic purity is assumed, without contemplating the possibility that an individual may self-identify with multiple ethnic groups or none; (2) it is applied ethnocentrically exclusively to others (i.e. the others are the ones with *weird* customs); and (3) it is used to mask a 'difference' that is in fact inequality, subjugation, and discrimination of minorities.

A significant problem in pain research is the stereotypical, methodologically inconsistent, and widely diverse use of racial-ethnic-cultural labels (Bernstein and Patcher, 2003; Finley et al., 2009; LeResche, 2001; McGrath and Finley, 2003; Zatzick and Dimsdale, 1990). In a critique of some 'classic' research studies on pain and culture, psychiatrist and anthropologist Kleinman and colleagues (1992, p. 2) argue that these labels are dehumanizing, create caricatures instead of people, and fail to address pain as 'an intimate feature of lived experience of individuals in the context of their local social world and historic epoch'. Widely used racial-ethnic-cultural labels are nation-state labels (e.g. 'Chinese' with 1.6 billion people), designating thousands of millions of individuals who have little in common other than politically and militarily drafted international borders. The same applies to pan-ethnic labels such as Hispanic or Latino, which are contested and yet used as political manoeuvres to provide health care to minorities that cannot afford them otherwise (Duany, 2011; Santiago-Irizarry, 2001). In addition to a general lack of theoretical frameworks in studies of culture and pain (Kristjansdottir et al., 2012), the difficulties in systematically delineating ethnic groups make it challenging to develop comparative meta-analyses of findings, synthetic summary statements, and clinical guidelines (Bernstein and Patcher, 2003; Finley et al., 2009; Garro, 1990; Zatzick and Dimsdale, 1990). Finally, because of its clinical orientation, this chapter is not representative of contemporary work on pain in the humanities and the social sciences, which has abandoned a cross-cultural comparative perspective and has instead focused on the deeply personal, subjective and

intersubjective nature of pain experiences. For the interested clinician, a selected list of publications is included in the online supplementary materials, which also includes patients' own published accounts.

## Paediatric pain in cultural context

As in research with adults, findings on the relationship of culture and pain in children are inconclusive and do not support specific clinical recommendations (Bernstein and Patcher, 2003; Finley et al., 2009; Pfefferbaum et al., 1990; Rosmus et al., 2000; Zeltzer and LeBaron, 1985). Determining cultural influences on paediatric pain is more complex because of the additional variability introduced by parent-child relationships (e.g. development, socialization, and family context). There is a scarcity of research studies examining the relationship between culture-ethnicity and pain in children, and a total dearth of work that examines culture-ethnicity among paediatric chronic pain patients, despite the importance of the social context for its treatment (Fortier et al., 2009). In addition, only one study has examined cross-cultural differences on children's pain perceptions with an experimental methodology (Evans et al., 2008). In what follows, for the sake of clarity and despite the reservations that I have raised, I use the ethnic-cultural-racial labels that the authors themselves use.

## Children's pain perceptions and experimental pain

Regarding the influence of culture on pain perception in experimental and non-experimental pain research, our current understanding can be summarized as follows. First, numerous studies are plagued with theoretical and methodological problems. Second, no agreement exists on how culture may influence pain perception, and on what aspects of pain perception may be influenced. Third, adult experimental and clinical pain research show that non-sensory aspects of pain, such as unpleasantness, tolerance, and intensity, may be susceptible to ethnic-cultural influences, but no cross-cultural evidence has been found in the neurophysiologic detection of pain (Edwards et al., 2001; Green et al., 2003; Zatzick and Dimsdale, 1990: 554). Finally, despite the abundant literature with adults, only one study has examined ethnic-racial differences with children in a laboratory setting. In this study of three pain tasks with 123 healthy children (mean age was 12.9 years) in the US, Evans et al. (2008) found that African American children were no more or no less sensitive to pain than Caucasian American children, and no more likely to use a specific coping strategy. However, when coping (attending versus distracting) and race were considered together, significant differences emerged. For African American children, attending was associated with lower levels of pain and lower pain sensitivity, while for Caucasian Americans, distracting was associated with lower levels of pain and lower pain sensitivity.

## Children's descriptions and understandings of pain elicited in interview studies

With the exception of Abu-Saad's research (1984a, 1984b, 1984c), most interview studies of children's pain descriptions and understandings in clinical and non-clinical contexts have taken a developmental perspective without consideration to cultural differences, despite the fact they have often been conducted in various countries. The lack of a cross-cultural perspective makes it unclear whether reported non-developmental differences are due to culture, context

of the study, or the methods used. Gaffney and Dunne's study (1987) illustrates this difficulty: the authors reported that some Irish schoolchildren viewed pain as punishment. However, because such views of pain have not been found by other studies, researchers have speculated that it may have to do with the religious context of the schools in the study or with some aspect of the test procedure (Esteve and Marquina-Aponte, 2011; McGrath, 1995).

Abu-Saad's influential research has examined cross-cultural differences in children's pain descriptions and understandings with Arab American, Asian (Chinese) American, Latin American, and Dutch schoolchildren (Abu-Saad, 1984a, 1984b, 1984c, 1990; Abu-Saad et al., 1990). Overall, Abu-Saad and colleagues found that the range of physical and psychological causes of pain did not differ widely amongst cultural groups. Some cross-cultural differences were found in the use of sensory, affective and evaluative terms to describe pain; the description of the causes of pain; and the types of aches reported. Intracultural differences were also found, for instance, in the intensity scores assigned to pain descriptions by children with and without hospital experience. Revealing a more complex description, Abu-Saad also identified similar and recurring intracultural gender differences in several cultural-ethnic groups. Within their respective cultural-ethnic group, Arab and Asian American girls reported more frequently psychological causes of pain, different feelings when in pain (e.g. girls reported more often feeling embarrassed) and different pain coping mechanisms (e.g. girls preferred to be comforted).

Three recent studies of children's pain experiences and descriptions have focused on smaller populations and situations. As with previous research, they have revealed minor cultural differences. Cheng's (2003) study of southern Taiwanese children's pain experiences reports that crying does not necessarily involve vocalizations, but may be limited to facial expressions. Cheng relates this finding to cultural norms that vocal crying is inappropriate in southern Taiwan. Cheng also reports that some Taiwanese children perceived that their parents lied to them about the possibility of experiencing pain during hospitalization. Jongudomkarn and colleagues' (2006) study of north-eastern Thai-Isan children living with pain found that Thai-Isan children often described their pain as torturing, and that their pain experiences may not be extrapolated to children of different cultures in central and southern Thailand. Finally, and also involving Thai children but with a Thailand versus US cross-cultural comparative design, McCarty et al. (1999) analysed six stressful situations in terms of cultural differences, coping goals, and type of coping (overt versus covert). The authors reported that culture did not have a monolithic effect on child coping, but interacted with other variables such as stressor situation, gender, and age. The two groups differed in some situational contexts more than others, depending on the cultural salience of the situation.

Taken together, the evidence emerging from cultural studies of children's pain descriptions, experiences, and understanding of pain reveals more cross-cultural similarities than differences, and points to significant intracultural differences depending on gender, age, stressor, and situation. Culture is not a monolithic influence on the totality of the pain experience: specific cultural practices interact with other variables to influence particular components of the pain experience. In addition, these studies debunk the wrongly assumed internal cultural homogeneity within nation-states and ethnic groups, and expose the ease in which cultural diversity

may be acknowledged in Western countries but ignored in non-Western ones. They illustrate the importance of avoiding cultural stereotypes such as 'Children from culture X feel Y pain no matter what situation, what happens, what is said, who is present, what age, what gender, and so on and so forth' (see the later discussion of situational factors in acute paediatric pain).

### **Children's clinical pain score scale rating self-report studies**

Three studies reveal minor cultural differences: Zeltzer and LeBaron's (1985) study of Anglo American and Mexican American adolescents (ages 10–21) with cancer in the US, Pfefferbaum et al.'s (1990) study of Anglo and Hispanic children (ages 3–15) with cancer in the US, and Alwugyan et al.'s (2007) study of Kuwaiti children (ages 6–12) from countries in the Gulf (Kuwait and Kingdom of Saudi Arabia), Egypt, and the Levant (Lebanon, Syria, Jordan, and Palestine). At the same time, all three studies report intracultural differences: Zeltzer and LeBaron report differences between the two groups of Mexican Americans (e.g. rural versus urban lifestyles, and clinic differences between treatment centers); Pfefferbaum et al. report differences between Hispanic children and their parents; and Alwugyan et al. report differences according to socioeconomic factors, such as family income and educational level of the mother.

The intracultural differences in the three studies raise a critical issue that underlies much of the research on children's pain and culture, namely the need to provide a complex description of the social context in which children are socialized and acculturated (e.g. assimilation into the majority group). Child development does not occur in a social vacuum. From the moment of birth, an infant inhabits a sociocultural world (Pillai Riddell et al., 2007; Pillai Riddell and Racine, 2009), a fact illustrated by research showing that infants as young as 2 or 4 months old show cultural differences in acute pain responses (Lewis et al., 1993; Rosmus et al., 2000). Furthermore, children are not raised by parents within a self-contained family context, but within and in relation to social contexts such as the village/city, the school, the peer group, extended family, the state, and the socioeconomic forces that affect parents and families in terms of income, occupation, and education. Consequently, socialization/acculturation is not a unilineal process, but one that results from children interacting with parents, relatives, children and teachers in school, the public media, health practitioners, and other individuals and institutions (Craig and Pillai Riddell, 2003). In conclusion, these studies find no significant intercultural differences in clinical pain reports and instead identify intracultural differences, such as generational, rural/urban setting, socioeconomic, minority group membership, and the institutional culture of each clinic.

### **Children's pain responses and observational measures**

Observational studies of children's pain responses provide similar findings. There are no significant overall cross-cultural differences, but minor differences emerge when an abstract definition of culture is abandoned, and culture is considered as interacting with other factors, such as the training of health care professionals, ethnicity of the observer/pain rater, parental socioeconomic class, parental level of literacy, and phase of the medical procedure.

Some cross-cultural design observational studies found no remarkable cultural differences, such as Pfefferbaum et al.'s (1990), while others have found some minor differences. In an study examining Dutch and US children with cancer undergoing bone marrow aspirations (age 8 months to 18 years 7 months) in their respective countries, van Aken et al. (1989) found subtle differences between the two groups according to phase of the medical procedure (preparatory, bone marrow aspiration, recovery). The authors discuss several explanations to account for these subtle differences, including cultural and contextual factors (i.e. differences in hospital setting, presence/absence of parents, and adult behaviours).

Bohannon (1995) examined pre- and post-surgery pain differences between African American and Anglo American children (ages 3–7) in the US using behavioural, self-assessment, and physiological measures. Bohannon found that African American children were significantly rated lower on observed pain behaviours, despite the fact that children rated their pain similarly. Bohannon discussed different interpretations: (1) non-linguistic based pain scores may be less subject to cultural–ethnic differences or may indicate universal aspects of pain; (2) African American children may express their pain differently when compared to Anglo American children; (3) the observational measure (Children's Ontario Pain Scale) may be better suited to detect pain behaviours of Anglo American children; (4) the examiners, whose ethnicity was not controlled, may have exhibited a bias.

Three studies relied on Blount et al.'s original or revised Child Adult Medical Procedure Interaction Scales (CAMPIS) (Blount et al., 1989, 1990, 1997) to examine procedural pain with children from different cultural backgrounds. However, the lack of a cross-cultural design requires caution when interpreting the results. Overall, authors found great consistency between their findings and previous research. Salmon and colleagues' (2002) study of Australian children (ages 2–7) of European, Middle Eastern, Asian, and Pacific Island descent undergoing voiding cystourethrograms found no cultural differences. Pedro et al.'s (2010) study of Portuguese children (ages 3–6) undergoing routine immunizations found some differences. However, underscoring the exploratory nature of their study, Pedro et al. contemplated that these differences could be due to cultural differences and/or lack of specific training of professionals and parents. Mahoney et al.'s (2010) study of venipunctures among mostly white European children (ages 7–16) in the UK found that humour and non-procedural talk were more common in the UK when compared to studies in the US. Furthermore, they found that adult behaviours such as apologizing, criticizing, and making empathic comments were rare; and children's verbalized pain and fear were common. Mahoney et al.'s findings raise an interesting issue: the possibility that cultural differences may not necessarily involve different behaviours, but different distributions and different frequencies of similar behaviours.

Finally, Rosmus et al.'s (2000) and Lewis et al.'s (1993) cross-cultural design observational studies of infant pain provide a new understanding of cultural difference and infant pain response. They highlight that cross-cultural variation may occur earlier in life than previously assumed. In a study of 4-month-old Japanese and American Caucasian infants undergoing routine immunizations in the US Lewis et al. (1993) found that Caucasian and Japanese infants did not differ in pre- and post-inoculation cortisol increase, but Caucasian American infants were more *behaviourally* reactive to pain than the Japanese counterparts. The authors emphasized

that Japanese infants are not less affected by stress. Instead, they suggested two potential explanations for the differences in pain reactivity, one biological (i.e. genetic basis of temperament) and one cultural explanation related to socialization (i.e. Japanese infants are kept in close proximity to the parents, which may lead to a smaller need of signalling of distress).

Rosmus et al.'s (2000) examination of the behavioural pain response of Chinese and non-Chinese Canadian 2-month-old infants undergoing routine immunizations found that Chinese Canadian infants showed a higher degree of behavioural reactivity than non-Chinese. Rosmus et al.'s findings go in the opposite direction of Lewis et al.'s findings (non-Japanese infants showed increased reactivity), demonstrating that a globalizing category of 'Asian' is unsuitable.

Rosmus et al. underscored that the Chinese/non-Chinese groups also differed significantly according to socioeconomic status (i.e. parental education and occupation). The authors conducted an impressive discussion that brings together cultural, socioeconomic, communication styles, and situational factors, to account for the differences in infant pain reactivity. For instance, infant arousal state may be influenced by the mother's communication style, which in turn, may be influenced by the mother's socioeconomic status. Since mothers may feel that their infant's behaviour reflects on how good/bad a mother she is, mothers of varying occupation and education will likely hold different values and expectations about how to present their infants to (unknown) others. Furthermore, parental education and occupation may interact with situational factors related to the logistics of the study, such as the ability (or lack thereof) to read, write, and give reports. In brief, Rosmus et al.'s study demonstrated that cultural differences are already present at a very early age, and, in line with studies discussed earlier, that culture does not have a monolithic effect on child pain behaviour, but intersects with other variables such socioeconomic status, communication style, and situational factors.

### The sociomedical and socioeconomic contexts of paediatric pain

If culture is an ethereal concept that is difficult to define, the consequences of cultural differences are palpable in the specific sociomedical and socioeconomic contexts of paediatric pain. Specifically, I discuss the impact of professional and institutional cultures, as well as health care disparities, on children's pain.

Regarding its sociomedical context, the assessment and treatment of paediatric pain are contingent on parents' and health professionals' attitudes and beliefs (Post et al., 1996). Pain assessment varies according to whom is observing it, in clinical practice (Davitz et al., 1976) and in research (Bernstein and Patcher, 2003; Neuman, 1996; Post et al., 1996; Zatzick and Dimsdale, 1990). Furthermore, health professionals are not acultural beings, but have their own specific cultural–ethnic–religious background (Free, 2002). Finally, physicians and nurses are also members of specific professional cultures, having undergone a professional socialization process (Cicourel, 1987; Good, 1995), which makes them members of the particular subculture of a specific hospital/clinic/unit within the culture of a specific health care centre.

In Western and non-Western hospitals, institutional cultures and clinicians' beliefs often are the barriers to optimal pain management (Finley et al., 2009; McGrath and Unruh, 2007) in both developed and developing countries (Cohen and MacLaren, 2007; Craig et al., 1996; Finley et al., 2008; Forgeron et al., 2006, 2009; McCarthy

et al., 2004; Pillai Riddell et al., 2008). As Finley et al. (2008) note on the erroneous misconceptions about pain and opioid addiction, there is nothing Arab or Middle Eastern specific to them.

In terms of the socioeconomic context of paediatric pain, cultural–ethnic–racial differences place minority children as a vulnerable population when it comes to pain assessment and treatment (Kristjansdottir et al., 2012). Minoritized communities face overlapping problems such as racism, poverty, limited education, low income, limited proficiency in the majority language, lack of health insurance, high mobility due to migrant patterns associated with temporary jobs, and legal/illegal immigrant status. Furthermore, they have to overcome significant difficulties in access to care, in terms of financial affordability, living far from health care centres, and/or lacking transportation. Health care disparities have been qualified as a national and pervasive problem in the US (Williams and Organizing Committee of the Pain Disparities Special Interest Group of the American Pain Society, 2005). Although studies of sociodemographic disparities in paediatric pain management have yielded inconsistent results (see Ezenwa and Huguet, Chapter 65, this volume), disparities in adult pain (Green et al., 2003) and general health care disparities for minority children have been documented. Thus, it is not far-fetched to assume that minority children share the health care disadvantages of their parents.

Disparities in children's health have been reported within three common paediatric health conditions: asthma, oral health, and obesity/type 2 diabetes (Fuemmeler et al., 2009). Access to health care is also an obstacle for uninsured children, who are disproportionately minority children. Fuemmeler et al. also report that Hispanic children are more than twice as likely to be non-insured in the US. Hispanic children are also the least likely to be insured with the numerous risk factors and consequences (Flores et al., 2006). In a review study of barriers to health care for Latino children in the US, Flores and Vegas (1998) reported that Latino children are more likely to be poor, the most uninsured, and have parents with the lowest education attainment. In addition, Latino children experienced provider-related barriers such as reduced screening, missed vaccination opportunities, decreased likelihood of receiving prescriptions, suboptimal management plans, inadequate communication and patient education, and perceptions of negative attitudes. It is fundamental then to acquiesce that social inequalities and racism, and not culture per se, are often the culprits of profoundly unjust health disparities.

## Paediatric pain in communicative context

### Paediatric acute pain and communication

In the same way that culture and ethnicity influence children's pain experiences, a number of contextual factors—also referred to as situational or environmental—influence pain experiences. Contextual factors are discussed elsewhere in this volume in chapters on distraction (Cohen et al., Chapter 53), pain and the family (Birnie et al., Chapter 12), and the various measurement chapters—especially with non-verbal populations (e.g. Lee and Stevens, Chapter 35; Chorney and McMurtry, Chapter 37). However, a way to remember key contextual factors includes using interrogatives (what, when, who, whom, where, and how). Adult (parent and staff) and child behaviours are highly interactive, affecting each other in subtle, susceptible, and almost-immediate ways. Because of this, current and future studies are moving beyond who is present during a painful procedure, to

examine also what they are communicating verbally and non-verbally, when, who, to whom, where, and how (Table 11.1).

### Paediatric chronic pain and communication

Children with chronic pain often feel that clinicians do not hear, understand, or believe them (Carter, 2002; Nutkiewicz, 2008). In an interview study of 32 adolescents with non-malignant chronic pain (ages 14–18) in the US, Nutkiewicz (2008) remarked that clinicians ignore the experiential component of the pain and the child's lived experience, and are not attentive to information that may not be discernibly or explicitly clinical. In addition, adolescents find themselves continually re-telling their pain stories in multiple unrelated visits to different clinicians. Children's perceived lack of physician understanding reinforces their frustration, loss of potential, sense of isolation and difference from peers; and lowers even further their expectations that clinicians or parents can help them (Meldrum et al., 2009).

In a narrative study of children with chronic pain and their families in the UK, Carter (2002, 2004) described how children experience 'referral fatigue' in their 'diagnostic quest' (see also Lillrank, 2003; Ong et al., 2004), from one specialist to the next, as well as professional 'ventriloquism,' where 'the child's words are reinterpreted and mistranslated through the professionals' own paradigmatic understanding of the narrative' (Carter, 2002, p. 36).

Children's negative experiences of communication inside the clinic/hospital are missed opportunities to incorporate the richness of children's own pain narratives into clinical decisions. Based on a qualitative analysis of the narratives of 45 children with chronic pain attending a US multidisciplinary tertiary care specializing in pain, Meldrum et al. (2009) identified five common themes in children's narratives: hiding pain from parents and friends; a sense of isolation and difference from peers and classmates; pain as an obstacle to personal activities; fears about how pain will affect the future; and perceived lack of physician understanding. These themes are articulated in six different narratives or plotlines: the constant patient, the invalid, the weary soldier, the stoic, the positive thinker, and the decision-maker. Meldrum et al. (2008) also identified a functioning strategy developed by the children themselves, 'getting on with life,' which involves ignoring the pain and trying to keep going. These authors also provide additional support to two self-developed strategies identified by Hunfeld et al. (2001): 'planning ahead,' which involves deliberately organizing activities while reducing stress, and 'body awareness,' which involves becoming aware of one's body while distracting oneself from the pain. A further discussion of persisting pain can be found in Chapter 32 by Mherekumombe and Collins.

## Conclusion

In this chapter, the complexity of examining the relationships between culture and pain, and communication and pain has been highlighted. Neither pain nor culture and communication are amenable to 'easy answers and fixes.' Indeed, 'easy answers and fixes' lead to ignoring or stereotyping cultural and communicative differences. On the contrary, the variability of cultural and communicative contextual factors only adds to the variability of subjective and deeply personal pain experiences.

We are beginning to understand how cultural and communicative factors influence pain and what aspects of pain they influence. Cultural and communicative factors affecting pain are characterized

**Table 11.1** Contextual variables based on interrogatives

<b>What<sup>a</sup></b>	<p>Praising the child is neither related to child coping nor distress</p> <p>Empathic and apologetic statements are positively related to child distress</p> <p>Reassurances fail to diminish displays of child and infant distress, and may magnify them</p> <p>Adult promoted attention manipulation (e.g. passive and active distraction) are beneficial in child coping and reducing pain</p> <p>When the distraction intervention requires too much attention, the distress may interfere with the child's ability to focus on the distraction</p>
<b>When</b>	<p>Children's distress is likely to be preceded and followed by adult distress promoting behaviours (e.g. reassurances) in what seems a circular relationship</p> <p>Children's engagement in coping behaviours, such talk unrelated to the painful procedure, humour and coping statements, is also preceded and followed by adult coping-prompting behaviours</p> <p>Child distress and coping, and adult behaviours change according to the phase of the medical procedure</p> <p>Type of adult coping promoting and child coping behaviours correlate within a specific phase, but not across phases</p>
<b>Who</b>	<p>Nurses' increased coping promoting behaviours are associated with an increase in parental coping promoting behaviours</p> <p>Whereas nurses' and physicians' behaviours are uniformly negatively associated with child distress, some parental behaviours are associated with child distress</p>
<b>Whom</b>	<p>Whereas the same behaviour of adult non-procedural talk to another adult is neutral, when addressed to the child, non-procedural talk is child coping promoting</p> <p>Despite the developmental changes in children's pain expression, it remains to be determined whether observational measures of children's procedural pain need to be aged-normed</p> <p>Observational measures have shown good evidence supporting their validity from early childhood through late adolescence</p>
<b>Where</b>	<p>(1) Physical setting:</p> <p>Needle procedures should not be conducted in the patient's own room to preserve the room as a refuge</p> <p>Noise and light have a negative effect in the context of neonatal pain</p> <p>(2) Psychosocial setting:</p> <p>The evidence is inconclusive regarding the influence of parental presence child distress and behavioural outcomes, without distinguishing whether the father or the mother is the parent present, or whether one or both are present</p> <p>What parents do is more relevant than whether they are in the room vis-à-vis child distress reduction</p> <p>(3) The body as a means to communicate:</p> <p>Caregivers' instrumental, task-fulfilling (e.g. to restrain the child) touch is correlated with child distress, whereas supportive touch is not</p> <p>Caregivers may stand at a close distance but provide no supportive touch to the distressed child</p> <p>Combinations of supportive touch, posture, and movement (e.g. skin-to-skin kangaroo, rocking, holding, and to a lesser degree, bouncing, patting, kissing, rubbing, and hugging) have been shown to reduce preterm, neonate, and infant distress</p> <p>The evidence of the efficacy of handholding is inconclusive, although some evidence points that it depends on who is holding (nurse versus parent) the child's hand</p>
<b>How</b>	<p>The production of a parental linguistic expression can vary widely in terms of tone, pitch, loudness as well as in terms of the non-verbal communication accompanying it</p> <p>The lack of attention to non-verbal communication may explain the contradictory findings regarding whether parental empathic supportive talk is related to increased or decreased child pain during painful procedures</p> <p>Ordering the child to relax with a forceful imperative like 'Relax!' and 'Breathe!' is a different action when compared to parents modelling deep breathing</p> <p>Facial expressions of emotion (happy versus fearful) may be more salient feature than vocal tone (rising versus falling final intonation) to children</p>

<sup>a</sup> See Birnie et al. (Chapter 12) and Cohen et al. (Chapter 52) for further discussion.

by their *variability* (e.g. each cultural and communicative context is somewhat different), *specificity* (e.g. pain experience occurs to a specific individual, in a specific situated context, at a specific time in his/her life), *multiplicity* (e.g. multiple cultural and communicative factors are operating simultaneously, interacting with each other, and mediating pain experiences), and *time sensitivity* (e.g. immediately preceding talk may influence subsequent pain responses). Rather than creating checklist inventories, clinicians can develop observational and interview tools to consider the multiple and simultaneous factors that influence pain. It is fundamental that clinicians become aware of their own cultural biases, learn that culture, ethnicity, and race cannot be assumed just by looking at the patient, and that no cultural recipe can substitute observing the patient and listening to him/her.

### Case example

In a biopsychosocial approach to paediatric pain, eliciting children's (and parents') pain accounts is fundamental but challenging. Clinicians have two interlocutors at any given time, parents can take over the conversation, and disagreements arise between parents and children. There are small, practical communicative strategies to overcome these challenges (Clemente, 2009; Clemente et al., 2008, 2012). In the following case, a 12-year-old girl with recurrent stomach pains produces an account. The clinician uses a variety of strategies to support and encourage her. The clinician uses a question preface (lines 1–11) and broad open-ended questions and prompts (lines 13,

16, 22, 28, 33). When broad questions are met with prolonged silence (lines 26 and 35), the clinician retains the girl as respondent by asking questions that require only a yes/no answer (lines 36, 39–41). Despite her many silences and pauses, the clinician has given the girl ample time to answer. At the same time, giving ample time and broad directions have the risk that the child may get lost, which occurs in lines 18 to 20. In eliciting children's pain accounts, a balance may be required between giving not enough guidance (e.g. using broad questions that do not constrain patients' accounts but may result in disoriented patients who do not know what the clinician wants to hear) and too much guidance (e.g. narrow questions that constrain patients' answers to merely 'yes/no') (Figure 11.1).

## Acknowledgements

I would like to express my gratitude to my postdoctoral advisor Dr Lonnie K. Zeltzer at the D. Geffen School of Medicine at UCLA, and to Dr Carl von Baeyer, my advisor in the PICH (Pain in Child Health) Research Strategic Training Program of the Canadian Institutes of Health. My participation as an international post-doctoral trainee in the PICH program was made possible by the generous support of the Mayday Fund. I also wish to thank Dr Bonnie Stevens for her many contributions to this chapter and to Dr Marcia Meldrum, Dr Maria Katz, Mary-Caitlyn Valentinsson, and Eugene Danyo for their meticulous reading of this chapter.

1 DOC: Nice to meet you too.  
2 (0.5)  
3 DOC: allo Madame?,  
4 (0.3)  
5 DOC: nice to meet you, (1.1) so I read  
6 through your medical records, and  
7 reviewed your questionnaires,  
8 MOM: Oh okay.  
9 DOC: I wanted to know a little about what's  
10 been going on from your point of  
11 view.  
12 (0.6)  
13 DOC: -> what brings you here.  
14 (1.8)  
15 PAT: Um (that I don't feel good)?  
16 DOC: -> Okay, keep going.  
17 (0.5)  
18 PAT: U:m (2.1) um (0.5) you're gonna try  
19 to help me?  
20 DOC: hh yea that's t [rue:  
21 MOM: [h  
22 DOC: -> Tell me about not feeling good.  
23 (0.7)  
24 PAT: h um (0.5) I don't feel good a lotta  
25 times,  
26 (1.5)  
27 PAT: uh:: (1.3) what else.  
28 DOC: -> Okay whaddya mean by not feeling  
29 good.  
30 (0.6)  
31 PAT: Uh my stomach hurts?,  
32 (0.3)  
33 DOC: -> Okay, (0.6) tell me about your  
34 stomach hurting.  
35 (1.2)  
36 DOC: => hh you have Crohn's. Correct,  
37 PAT: Yeah.  
38 (0.6)  
39 DOC: => And you were diagnosed (1.0) you had  
40 stomach aches when you were three.  
41 Right?  
42 PAT: Yeah.

## CHAPTER 12

# Families and pain

Kathryn A. Birnie, Katelynn E. Boerner,  
and Christine T. Chambers

### Introduction

The family has long been acknowledged as an important social context where children learn about and receive support for their pain. When a child is in pain, it is the family who is responsible for the initial pain assessment and seeking appropriate evaluation and care. Families may inadvertently encourage the expression of pain and play a critical role in influencing their children's ability to cope with pain, both positively and negatively. Having a child in pain can also pose significant personal, familial, and economic strains. Therefore, consideration of the family is absolutely critical in the understanding of factors involved in children's acute and chronic pain experiences (McGrath, 2008). A concentration of research has continued since the last comprehensive review on the topic was published (Chambers, 2003). This chapter considers relevant theoretical models and summarizes current major research themes regarding the role of the family in both acute and chronic paediatric pain. Two illustrative case examples are provided and key areas for future research are identified.

### Theoretical frameworks: families and pain

Recent work has situated family factors and relationships as one of many important determinants in a biopsychosocial formulation of pain communication (Hadjistavropoulos et al., 2011). Other broader theories related to parent-child interactions and the family environment have been applied to the pain context and have also guided research in the field; most notably operant conditioning/social learning theory (Bandura, 1977), theories of family systems (Turk et al., 1987), and attachment (Porter et al., 2007). Several pain-specific theories have also been proposed, such as the empathy model for others' pain (Goubert et al., 2005).

An integrative model of parent and family factors in paediatric pain was proposed by Palermo and Chambers (2005). This model (Figure 12.1) emphasizes the importance of multiple levels of family assessment, and situates individual parenting variables (e.g. parenting style, parental reinforcement) within a broader context of dyadic variables (e.g. quality of parent-child interaction), embedded within the global familial environment (e.g. family functioning). The model highlights reciprocal interactions of individual child and parent factors, with dyadic (parent-child), and familial levels in influencing children's reported pain severity, associated

functioning, and successful coping. The model was expanded by Evans and colleagues to more clearly delineate the specific contributions of various child and parent pain and functioning variables (Evans et al., 2008ab). This theoretical framing provides a basis for empirical work on the role of the family described in the following sections.

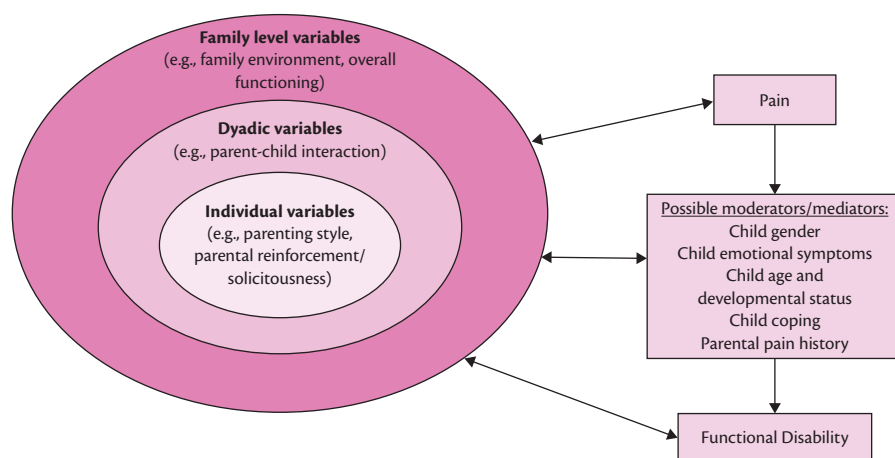

### Acute pain: families and pain

#### Case example

Ryan is an 8-year-old boy who requires frequent blood work for monitoring of an endocrine disorder. He experiences considerable distress in the days leading up to his blood work. In the past he has needed to be restrained by one of his parents and/or a member of the medical staff. During the procedure Ryan's mother is visibly very anxious and tries to comfort him by saying 'You'll be okay. It will be over soon'. At the last appointment, Ryan's resistance was so strong that the medical staff were unable to complete the procedure. Ryan's parents and medical staff have become increasingly frustrated with his behaviour and have begun to avoid telling him in advance when he will need blood work, further increasing Ryan's distress and distrust around procedures. Ryan's endocrinologist refers him and his family to the Paediatric Health Psychology Service, where Ryan receives instruction in cognitive-behavioural pain management coping strategies, including distraction and deep breathing. His parents learn how they can best coach Ryan during the procedure, including prompting him to use deep breathing and use of distracting talk. The family, in collaboration with Ryan and the psychologist, develop a plan for preparing him for procedures (i.e. deciding how much advance notice Ryan needs for procedures) and for rewarding him for his hard work after procedures (i.e. going to get an ice cream cone). The family also learns about the value of using topical anaesthetics, such as EMLA®, as part of his pain management plan.

### Parental assessment of acute pain

Children experience numerous acute painful events across childhood, typically in the form of everyday minor injuries (Fearon et al., 1996). Often, it is the parent who assesses the child's pain and

**Figure 12.1** Integrative model of parent and family factors in pediatric pain. Reproduced from Palermo, T. M. and Chambers, C. T., Parent and family factors in pediatric chronic pain and disability: An integrative approach, *PAIN*®, Volume 119, Issues 1–3, pp. 1–4, 2005. This figure has been reproduced with permission of the International Association for the Study of Pain® (IASP). The figure may NOT be reproduced for any other purpose without permission.

makes decisions regarding management. Children also frequently experience painful medical procedures, either for routine immunizations or as a result of diagnostic and/or treatment procedures (Stevens et al., 2011). While health professionals are involved in assessing the child's pain in the medical setting, it is typically the parent who assumes the primary role in assessing their child's pain. Health professionals frequently rely on parents to provide information relevant to pain assessment, for example, the extent to which the child's current (pain) behaviour differs from their usual behaviour. This information is particularly important when child self-report is not available.

Parents are typically asked to provide observer ratings using self-report pain assessment tools used with children (Stinson et al., 2006). Parents generally underestimate their children's pain, although the reasons for this are not clear (Chambers and Craig 1999; Chambers et al., 1998; Goubert et al., 2009; Kelly et al., 2002; St Laurent-Gagnon et al., 1999). However, parents are generally more accurate in their estimation of children's pain as compared to health professionals, including physicians and nurses (Boerner et al., 2013). The extent that parents and children catastrophize about the child's pain may play an important role in parental pain assessment. In parents, higher levels of pain catastrophizing have been related to higher child-pain ratings by parents, and better agreement between parent and child pain ratings (Goubert et al., 2009). In children, lower levels of pain catastrophizing have been related to better agreement in parent-child pain ratings (Vervoort et al., 2009). Some situations may increase the challenge of pain assessment for parents. For example, while parents are relatively good at detecting when their children are genuinely experiencing or pretending to have pain, they have difficulty in accurately detecting when their children are suppressing pain (Larochette et al., 2006). More research is needed examining the various psychological and contextual factors that influence parent acute pain assessment and to distil this work into measures and approaches maximizing parents' ability to provide important information about pain assessment.

### Parental behaviour and acute pain

Children's experiences during acute painful events can have an impact on their memories of the painful experience and their reactions to future painful events (Chen et al., 2000; Noel et al., 2010). Repeated negative interactions in the context of pain have the

potential to significantly impact children's later health care usage (Pate et al., 1996). Parent variables have played a critical role in children's coping and distress during painful medical procedures. It is now well accepted that parents should be present with their child during painful medical procedures, and the focus of research is on how and why parents' behaviours during medical procedures relates to their children's pain experiences.

Blount and colleagues (Blount et al., 1990, 1991, 1997) investigated the relationship between parent behaviours and child distress and coping by providing detailed coding of child and parent verbalizations during painful medical procedures. Specific parent behaviours are associated with decreases or increases in child distress, respectively classified as 'coping promoting' or 'distress promoting'. Behaviours classified as 'coping promoting' included non-procedural talk, suggestions on how to cope, and use of humour. A well-established, but seemingly, counterintuitive relationship between several parent behaviours and child distress was identified (e.g. empathy, reassurance). Reassurance is the most common parent behaviour exhibited during painful procedures (Cohen et al., 2002); yet it has consistently been linked to higher levels of child pain and distress, both in clinical and experimental research (Chambers et al., 2002; Taylor et al., 2011). The specific mechanisms through which reassurance promotes child distress and pain during acute painful medical procedures are not known; however, it appears that parental reassurance serves as a signal to the child that the parent is anxious, thereby triggering distress and pain in the child (McMurtry et al., 2006). Children report higher fear during parental reassurance than during parental distraction, and perceive their parents as being fearful or worried when they are providing reassurance to the child, especially when it is offered with a fearful facial expression and in a rising tone, indicative of uncertainty (McMurtry et al., 2010).

The tendency to catastrophize about pain has been proposed to play a role in parents' responses to their children's pain. Caes and colleagues (2011) found that parents' catastrophic thoughts about their child's pain were associated with a higher tendency by parents to restrict their child's behaviour (i.e. stop them from completing a painful experimental task). This relationship was mediated by parental distress, and was observed in parents of both healthy children and adolescents with chronic pain (Caes et al., 2011). Parental non-attending pain talk (i.e. utterances which did not focus on the

child's pain or the painful stimulus) was associated with increased facial displays of pain and self-reported pain in high pain catastrophizing children, although this difference was not observed in low pain catastrophizing children (Vervoort et al., 2011). Child pain catastrophizing was related to parental responses to children's pain, and was moderated by parent–child attachment (Vervoort et al., 2010). Future research in this area needs to utilize more sophisticated statistical techniques, such as sequential analysis and dyadic analysis, as well as consideration of parent non-verbal as well as verbal behaviour.

### The role of fathers

A major limitation of research on the role of the family in paediatric pain is the paucity of studies including fathers. Mothers are most often involved as they are accessible and are often identified as the primary caregiver. However, fathers play an increasingly important role in their children's lives and health care and, as such, are important to include (Phares et al., 2005). Moon and colleagues (2008) found that fathers showed better agreement with children's pain ratings than mothers. Moon and colleagues (2011) also examined parent's verbal behaviour while children completed the cold pressor task. Mothers and fathers generally did not differ in their proportions of attending and non-attending talk during children's pain; however, mothers used more non symptom-focused talk and commands, while fathers used more criticism (Moon et al., 2011). This work focused exclusively on comparing mother–father verbal behaviour; research is needed to also examine potential differences in use of non-verbal behaviour.

Sex differences exist in pain perception and responses to pain, which may be partially influenced by gender socialization (Myers et al., 2003). Gender socialization suggests that, through social learning processes such as modelling and reinforcement, children learn gender-specific behaviours that influence their responses to pain (Myers et al., 2003). Parents play an important role in teaching their children gender-specific behaviours (Langlois and Downs, 1980) and fathers tend to differentiate between male and female children more than mothers (Lytton and Romney, 1991). A survey of Finnish parents' perceptions of children's postoperative pain found that fathers were more likely than mothers to believe that their child should be able to independently cope with their pain, think that pain from surgery was acceptable, and believe that their children were capable of faking pain (Kankkunen et al., 2003). Additionally, boys were expected to tolerate more pain than girls. Researchers need to continue examining the unique role of fathers in paediatric pain, and avoid drawing conclusions about parent factors from research conducted primarily with mothers.

### Parents' roles in acute pain management

The importance of appropriate pain management for medical procedures in children has continued to receive attention. Clinical practice guidelines identify evidence-based pharmacological, physical, and psychological strategies for management of immunization pain in children (Taddio et al., 2010a, 2010b). Systematic reviews of psychological interventions in paediatric procedural pain management (Chambers et al., 2009; Uman et al., 2006, 2008) identify a number of effective cognitive-behavioural strategies for reducing pain (e.g. distraction, deep breathing) that parents can encourage or direct. Involving parents in coaching their child to cope during painful

#### Box 12.1 Recommendations for parents for managing procedural pain in children

- ◆ Prepare yourself and stay calm.
- ◆ Prepare your child by using age-appropriate words and be honest; children 5 years old and older should be told about the procedure at least 1 day in advance.
- ◆ Distract your child using age-appropriate strategies (e.g. toys, books, music, or videos).
- ◆ Encourage your child to take slow, deep breaths (e.g. with bubbles or pinwheels).
- ◆ Avoid words that focus on the pain or the procedure (e.g. 'It'll be over soon' 'You'll be okay'); it's better to talk about things not related to the procedure.
- ◆ Use other age-appropriate pain-relieving interventions, such as breastfeeding or sucrose for infants or topical anaesthetic creams.
- ◆ After the procedure, praise your child for a job well done.

procedures is also effective for reducing parental anxiety (Cohen et al., 1997). Parents can be instructed in how to: (1) prepare themselves and their child in advance of the procedure, (2) distract their child during the procedure, (3) provide physical comfort and other pain-relieving interventions (e.g. breastfeeding, topical anaesthetics), and (4) praise the child after the procedure (Box 12.1).

## Chronic pain: families and pain

#### Case example

Lauren is a 13-year-old girl with a 5-year history of recurrent stomach aches. When Lauren is seen by the Complex Pain Consultation Service, she has missed the past 6 weeks of school and reports daily stomach aches with an average pain intensity of 7 out of 10. Lauren's parents, Melissa and Doug, report considerable concern about her pain as well as frustration over how to best support Lauren. At the time Lauren's stomach aches worsened, Melissa was also home from work on disability as a result of a back injury she sustained in the work place. However, Melissa had recently returned to work, leaving Lauren unsupervised during the day. Lauren spends a typical day watching television, which she says helps to distract her from her pain. Melissa reported significant anxiety about Lauren's pain, and that she is frequently troubled by thoughts that perhaps Lauren will always have pain and never be able to return to school. Doug reports a strong family history of gastrointestinal symptoms, and acknowledged that he suffered from stomach aches as a child. The family reports considerable conflict about how to best manage Lauren's pain. Melissa feels that Lauren cannot return to school until her pain has improved or resolved, while Doug feels that Lauren just needs to 'tough it out' and return to school. Melissa reports waking up dreading the conversations they will have about Lauren's pain and whether Lauren will feel well enough to return to school that day.

### Aggregation of pain in families

Research is mixed in understanding the relationship between parental and child pain with some showing an increased risk of chronic pain for children who have a parent with chronic pain (Groholt et al., 2003; Saunders et al., 2007). Associations between parent and child pain may be site specific. Two large population-based studies demonstrated that parental headache, abdominal pain, and back pain were predictive of the same pain sites in children (Groholt et al., 2003; Saunders et al., 2007). Additionally, a dose–response relationship in the number of pain sites reported by mothers was associated with a greater number of pain sites in children (Saunders et al., 2007). The influence of parental pain models may be sex specific with a higher concordance rate of parent–child pain among mothers and daughters; however, data for fathers were incomplete (Evans et al., 2010). A prospective study supported a relationship between parent and child pain experiences (Goodman et al., 1997); children of parents reporting four or more pain incidents over a 7-day period were at significantly increased risk for reporting a large number of total pain incidents, as well as clinically significant and disabling pain incidents. Together, these studies suggest a familial predisposition to pain sensitivity and reactivity.

Parent and child psychosocial and environmental factors may also account for associations between parent and child pain. Longitudinal examination over the first 6 years of life revealed that parent anxiety and child temperament during the child's first year were associated with later development of childhood recurrent abdominal pain (Ramchandani et al., 2006). Schanberg and colleagues (2001) reported associations between parental/familial pain history and current pain of children with chronic rheumatic disease were mediated by child pain catastrophizing. Maternal pain history has also been reported as a unique predictor of child functional impairment, although the impact of paternal pain history has not been examined (Kashikar-Zuck et al., 2008). Bruehl and colleagues (2005) found that children's recollections of parental pain significantly predicted the child's own chronic pain status and number of pain locations in adulthood, while objective parental history of chronic pain did not.

Altogether, findings from these studies demonstrate the potential role of risk factors contributing to parent and child pain, supporting the complex ways pain aggregates within families. Conclusions from these studies must be drawn cautiously as many are based on subjective retrospective report, employing varying definitions of intensity and frequency of parental and paediatric pain. Future research should continue focusing on longitudinal prospective designs that assess the possible influence of genetic, psychosocial, and environmental as risk factors for chronic pain.

### Impact of child pain on the family

Paediatric chronic pain significantly impacts on the family. Parents of children with chronic pain report high levels of parental role stress, anxiety and depressive symptoms, and social impact (Palermo and Eccleston, 2009). Rates of anxiety, depression, and somatoform disorders are higher among mothers of children with chronic pain as compared to mothers of healthy children (Campo et al., 2007; Evans et al., 2008b; Kashikar-Zuck et al., 2008).

Several studies have qualitatively explored parents' experiences caring for a child with chronic pain (Jordan et al., 2007; Maciver et al., 2010; van Tilburg et al., 2006). These studies describe parents'

experiences of fear, helplessness, and distress and describe parents as feeling powerless in attempts to help their child despite seeking resources and intervention. Parental adjustment is partially related to individual child and pain-related factors, with parents reporting higher levels of parenting stress with younger child age, pain chronicity, and child depression (Eccleston et al., 2004). Greater daily intensity of the child's chronic pain was predictive of greater maternal social restrictions, personal strain, and coping (Hunfeld et al., 2001). Parental factors, such as dispositional empathy and catastrophic thinking about their child's pain, also influenced parental distress in response to vignettes of children's pain experiences (Goubert et al., 2008). Addressing parents' psychological well-being is an area warranting greater research attention, as improved understanding of parental distress result in more effective management of children's pain and related disability (Palermo and Eccleston, 2009).

Siblings also worry about their sibling with chronic pain and became more considerate and compassionate toward them (Britton and Moore, 2002). Siblings reported confusion about their sick sibling's symptoms, wondering if they would develop chronic pain or what their own life would be like with chronic pain. Parents reported that siblings would sometimes compete for their attention. Research suggests that parents may alter their behaviour toward well siblings, excusing them from chores or offering special treats to assuage parental guilt associated with lessened attention (Jordan et al., 2007).

### Influence of parental beliefs, psychological functioning, and behaviours

Parental beliefs, functioning, and behaviours reciprocally influence children's pain (Palermo and Chambers, 2005). Parental beliefs about the aetiology of the child's chronic pain have influenced child pain outcomes and parent behaviours. Children whose parents subscribed to a biopsychosocial model of pain were more likely to have successfully resolved recurrent abdominal pain than children whose parents cited physical cause only (Crushell et al., 2003). Children whose parents believed their pain was 'medical only' reported the highest pain and functional disability (Guite et al., 2009).

Substantial research has focused on parental responses to children's pain. The Adult Responses to Children's Symptoms questionnaire (Claar et al., 2010; Van Slyke and Walker 2006) categorizes parental responses to children's chronic pain on three factors: (1) protectiveness (e.g. limiting the child's activities and responsibilities), (2) minimization of pain (e.g. criticizing), and (3) encouraging and monitoring (e.g. reassuring, distracting the child). Parental protectiveness has been associated with increased pain-related disability, child depressive symptoms, and longer pain duration (Claar et al., 2010). Parental protectiveness predicted greater somatic complaints among adolescents with chronic pain; as well as greater physical disability for adolescents who reported infrequent use of passive coping strategies (Simons et al., 2008).

Parent–child interactions during painful activities provide additional support for the influence of parental behaviours on children's pain. Sequential analysis of adolescents with chronic pain and their parents during an exercise task revealed that when parents made statements that discouraged child coping, the child was less likely to remain on task, which was significantly associated with functional disability and school absences (Reid et al., 2005). Similarly

to healthy children, children with chronic pain exhibited more symptom complaints during an experimental pain task when their parents attended to their pain, as opposed to when they distracted them (Walker et al., 2006). Clinical and experimental studies support the powerful influence of operant conditioning strategies of positive and negative reinforcement, whereby children's adoption of a sick role is continuously strengthened leading to increased disability and maladaptive coping.

Poorer psychological functioning of parents has been reported to negatively impact the child's reported pain and related disability (Logan and Scharff 2005; Palermo and Eccleston 2009), as well as influence parent behaviour. Mothers with greater psychological distress were more likely to seek physician consultation with child report of abdominal pain (Levy et al., 2006). Parental worry about the child's physical health was significantly related to child functional disability and parents' engagement in pain promoting behaviours (Guite et al., 2009). Additionally, greater maternal worry has been associated with higher perceived pain threat and limitations in family activities as a result of the child's pain (Lipani and Walker, 2006).

Parental pain catastrophizing strongly influences children's functioning. Mothers reported higher rates of pain catastrophizing than fathers, specifically a greater tendency to ruminate about their child's pain (Hechler et al., 2011). Negative consequences have been associated with parental catastrophic thinking about their child's pain, including increased parenting stress and parent psychological distress, as well as worsened child pain-related disability and school attendance (Goubert et al., 2006). As in acute pain, parent pain catastrophizing contributes significantly to parental responses to children's chronic pain (Hechler et al., 2011). Parental pain catastrophizing and protective responses to children's pain were unique predictors of school attendance and overall school impairment in adolescents with chronic pain, above the effects of adolescent pain intensity and depressive symptoms (Logan et al., 2012). Parental protectiveness mediated the relationship between parent pain catastrophizing and adolescent school functioning and attendance (Logan et al., 2012). Caes and colleagues (2011) demonstrated that parent distress mediated the relationship between parental catastrophic thinking and parents' tendency to restrict pain-inducing activity in children with chronic pain.

Children's psychological functioning and pain-related beliefs have repeatedly moderated the relationship between parent behaviours and child pain outcomes. The negative impact of maladaptive parent behaviours (i.e. solicitousness, protectiveness, minimization of the child's pain) on child's functional disability and somatic complaints were strongest for children with greater psychological distress (Claar et al., 2008; Peterson and Palermo, 2004). Furthermore, child pain catastrophizing moderated the relationship between parent symptom-related talk during a painful task and child symptom complaints; while the relationship between non-symptom talk and child symptom complaints was moderated by child perceived pain-related threat (Williams et al., 2010). Future research should continue integrating findings from experimental and clinic-based studies, and incorporate more complex multivariate analyses to allow stronger claims about the causal relationships between parental beliefs, functioning and behaviours, and child pain outcomes.

### Role of the parent-child relationship

Despite its theorized relevance (Palermo and Chambers, 2005), limited research has expressly examined the parent-child relationship

in paediatric chronic pain. Child autonomy, in particular, has predicted greater functional impairment among adolescents with chronic pain after controlling for pubertal status, pain intensity, and depressive symptoms (Palermo et al., 2007). Greater parent-adolescent conflict, poorer family functioning, and less age-appropriate autonomy predicted greater depressive symptoms for adolescents with chronic headaches (Lewandowski and Palermo, 2009). Interviews with children with chronic pain and their mothers suggested that limited autonomy reduced the child's sense of self-efficacy for pain and non-pain related activities, as well as decreased the likelihood of regular attendance at school and other activities (Evans et al., 2010).

Greater parent-adolescent relationship distress was related to increased adolescent distress and lower pain intensity, but not to adolescent functional disability (Logan et al., 2006). Parents reported closer relationships with their adolescent than healthy norms (Logan et al., 2006), a finding supported by interviews with parents and children with chronic pain (Jordan et al., 2007). This intensive parenting role is more akin to parenting a younger child (Jordan et al., 2007) and is consistent with the lower levels of age-appropriate autonomy reported by adolescents with chronic headache (Lewandowski and Palermo, 2009).

### Influence of family functioning

A recent systematic review revealed significant differences in family functioning between families of children with chronic pain and healthy controls (Lewandowski et al., 2010). Families of children with chronic pain generally reported poorer family functioning as exemplified through less family cohesion, less organization, greater conflict, and greater psychological distress. Poorer family functioning was also associated with increased child disability; however the relationship between family functioning and child pain was less consistent, possibly due to differences in how family functioning was measured across reviewed studies (Lewandowski et al., 2010). However, poor family functioning is not universal, as it appears to characterize a particular subgroup of children with chronic pain (Scharff et al., 2005) and is related to parental beliefs that the cause of the child's pain is 'medical only' (Guite et al., 2009). Altogether, these studies support the critical role of family factors in paediatric chronic pain and should be included as an important target for intervention.

### Role of family in interventions for paediatric chronic pain

Research supports the effectiveness of parental involvement in treatment of chronic pain. Of 25 randomized controlled trials included in a recent meta-analytic review, seven described involvement of parents in psychological therapies for paediatric chronic pain (Palermo 2009); however, the influence of parent/family involvement on trial outcomes was not explored.

Cognitive-behaviour therapy (CBT) has received attention as an effective intervention for paediatric chronic pain, often with family involvement as an important component for achieving and maintaining treatment gains (Robins et al., 2005). Parent involvement in CBT is based on principles of operant conditioning and modelling, such that child pain and level of functioning by parent reinforcement of independent adaptive coping by the child and limiting parents' attention to child pain behaviours (Palermo and Eccleston, 2009; Noel et al., 2012b). Box 12.2 provides a summary

**Box 12.2** Recommendations for parents for managing chronic pain in children

- ◆ Limit or remove attention from the pain.
- ◆ Be sure that your child goes to school each day.
- ◆ Help your child identify stress at home and at school.
- ◆ Provide attention and special activities on days when your child does *not* have stomach aches.
- ◆ Limit activities and interactions on sick days.
- ◆ Avoid talking about any pains or illness you have.
- ◆ Support your child in practising their pain coping strategies (e.g. relaxation, distraction).

of key messages to parents regarding behavioural pain management. Parents and children are engaged in a collaborative partnership where parents can both model and supportively 'coach' their child during treatment and for relapse prevention (Noel et al., 2012b; Palermo et al., 2009; Robins et al., 2005). CBT treatment protocols differ in the type and extent of parental involvement required, with some requiring joint attendance of the parent at a portion of treatment sessions (Robins et al., 2005) and others delivering content separately and concurrently to parents and children (Noel et al., 2012a; Palermo et al., 2009; for further discussion of CBT see Logan et al., Chapter 50, this volume). A randomized controlled trial comparing CBT to standard medical care for children with recurrent abdominal pain and their parents reported significantly reduced child pain and school absences for the CBT group immediately post-treatment and at 1-year follow-up (Robins et al., 2005). Significant reductions in parent pain-promoting behaviours were reported after a CBT intervention with parental involvement for children with recurrent abdominal pain (Noel et al., 2012a). Children with chronic pain and parents participating in an 8-week family CBT intervention online similarly reported significant reduced pain and activity limitations as compared with a wait-list control immediately post-treatment and maintained at 3-month follow-up (Palermo et al., 2009). Although some interventions address the importance of parents' own mental health (Noel et al., 2012a; Palermo et al., 2009), most do not assess parent psychosocial functioning. One study evaluating an interdisciplinary CBT programme reported significant improvements in parent anxiety, depression, and stress post-treatment that was maintained at 3-month follow-up (Eccleston et al., 2003). Children attending this programme also showed improvements in physical function and disability, anxiety, pain catastrophizing, somatic awareness, and school attendance (Eccleston et al., 2003).

Future research should explore the pathways through which family involvement exerts positive change on child pain outcomes. The role of parental involvement in more contemporary approaches to paediatric pain management, such as in acceptance-based treatments, is needed (Wicksell, 2007, 2008). Treatment studies should focus on the potential impact of changes in parent psychological functioning on children's pain-related outcomes, exploring the effectiveness of treatments for paediatric chronic pain designed to more directly address parents' emotional well-being (Palermo and Eccleston 2009).

## Conclusion

A large body of research showcases the relevance of the family, particularly parents, in paediatric pain. Findings support the influence of parent behaviours, psychological functioning, and beliefs about pain (e.g. pain catastrophizing) on children's acute and chronic pain outcomes. Several studies have innovatively integrated clinical and experimental methods of inquiry, representing a promising trend in the field bringing both scientific rigour and external validity to research findings. Correspondingly, parent involvement in interventions is largely based on modifying parental responses to children's pain using principles of operant conditioning. Family relationships and the family environment are revealed as influential frameworks both moulded by and contributing to children's pain experience. Because of the expanding literature on sex differences in parent responding to children's pain, the inclusion of fathers in future research should be prioritized. Consideration of a developmental framework is often omitted from current theories of pain and the family. Diverging trends are noted in paediatric acute and chronic pain research. Investigations of the family in paediatric chronic pain are expanding in scope, exploring the influence of individual, dyadic and familial level factors. In contrast, studies examining the family in paediatric acute pain are narrowing in scope, seeking a more detailed understanding of parent-child interactions. Pain and the family remains a very active and innovative area of inquiry, offering continued insight into the broader context within which children experience pain.

## CHAPTER 13

# Pain, social relationships, and school

Paula Forgeron and Sara King

### Summary

Although recurrent and chronic pain impacts the whole life of a child and or adolescent, little research has been conducted on social consequences of chronic pain for children and adolescents. Emerging research suggests that (1) peer relationships, including close friendships, of children and adolescents with chronic pain may be negatively impacted by pain and (2) social reactions from others can negatively impact the child or adolescent's pain experience. School functioning may also be impaired as a result of chronic pain. Clinicians should understand the challenges experienced by children with chronic pain and should attend to the social and school consequences of pain when working with this population. Although little research has examined interventions to manage the effects of chronic pain on school and social functioning, researchers have identified helpful strategies that may mitigate the negative consequences to social and school functioning associated with chronic pain.

### Introduction

Peer relationships and close friendships are a fundamental part of child development and become increasingly important as children approach adolescence. Peer relationships provide a milieu through which adolescents develop self-identity and values in the absence of adult monitoring (Rubin et al., 2005). Indeed, positive peer relationships and close friendships are associated with lower levels of depression and loneliness (Nangle et al., 2003), and positive school adjustment (Ladd et al., 1997). Close friendships can buffer the negative effects of peer victimization (Hodges et al., 1999) and negative family environments (Gauze et al., 1996).

School functioning is essential for positive development, as it has been linked to both academic and social success. Peer acceptance and close friendships have an impact on social functioning regardless of context, whereas teacher acceptance plays a critical role in school functioning for children and adolescents? Although typically developing children and adolescents often experience challenges in both school and social functioning, difficulties can be compounded for children and adolescents with chronic pain. Despite the importance of the relations between and among peers, friends, and school functioning for positive development, little is known about the impact of recurrent and chronic pain on these areas of functioning.

The goals of this chapter are: (1) to review the literature on social and school functioning for children and adolescents with chronic pain; (2) discuss strategies to ameliorate difficulties; and (3) highlight directions for future research.

### Social communication model of pain

The social communication model (SCM) of pain (Craig 2002, 2009) suggests that pain is a social phenomenon that is experienced within a social context. This model underscores the relationship between a child's or adolescent's chronic pain experience and their relationship with peers, friends, and school functioning. According to this model, the individual's pain expression is an iterative social process. Thus, peer, friend, and teacher responses to an adolescent's pain expression may impact either positively or negatively on the adolescent's pain experience. Conversely, the expression of pain by the child or adolescent may have an impact on his or her peers', friends', and teachers' interpretation and response to pain. This cycle of pain expression, interpretation, and subsequent pain expression may be as influential in the social interactions of children and adolescents with chronic pain as individual pain factors such as pain intensity. The SCM is reviewed in depth by Pillai Riddell et al. (Chapter 9, this volume).

### Background

#### Peers and friends

Research examining the relationship between peers, friends, and pain experience is in its infancy. Most research is based on general peer relationships (i.e. peer acceptance) as opposed to close friendships. When examining peer relationships of children and adolescents, it is necessary to differentiate between peer acceptance and close friendships. Peer acceptance (also defined as popularity) is a measure of general peer relationships based on unilateral liking and results in a feeling of belonging and inclusion (Buhrmester and Furman, 1986). Close friendships are based on mutual liking and provide one with intimacy and reliable alliance (Bagwell et al., 2001). Sullivan (1953) suggests that the need for peer acceptance is stronger for younger children, whereas the need for close friendships surpasses the need for general peer acceptance in adolescence. Thus, psychosocial adjustment in children may be linked more to

peer acceptance whereas for adolescents it may be linked more to close friendships (Erdley et al., 2001).

Pain first begins to interfere with social functioning by interrupting regular physical activities, leisure activities, and school attendance (Logan et al., 2008; Roth-Isigkeit et al., 2005). Missing physical and leisure activities in addition to missing school presents challenges for establishing and maintaining friendships, as these venues provide most of the opportunities for children and adolescents to interact with peers. Interruptions to activities and school absence can be problematic from a social functioning perspective, but the extent to which this is the case is not clear, as impact varies between individuals. Indeed, children and adolescents with chronic pain have fewer friends compared to healthy peers, but it is not clear whether this difference is significant (see Forgeron et al., 2010 for a review). Typically developing children and adolescents have an average of three to four close friends (Berndt and Hoyle, 1985). Although children and adolescents with chronic pain have been found to have fewer friends the actual number of friends they have compared to typically developing peers remains unknown (Forgeron et al., 2010). Perhaps more important is that it is not clear whether children and adolescents with chronic pain are at higher risk for having no close friends.

Although spending time with peers is necessary to foster friendships, time spent together may not be sufficient for good social functioning or the development of close friendships. For example, structured leisure activities have been linked to lower levels of aggressive behaviour (Mahoney and Stattin, 2000) and assist in the development of self-identity (Coatsworth et al., 2005). Therefore, adolescents with chronic pain who have withdrawn from structured leisure and sport activities may struggle with self-identification in relation to their friends and peers. Chronic pain was found to be a catalyst for adolescents to rethink their identity (Forgeron et al., 2011a). For example, children and adolescents with chronic pain may no longer identify themselves as a 'dancer' or 'football player', which may have a negative effect on self-identity. Recent research lends credence to this argument, as adolescents with chronic pain report lower self-esteem scores, increased loneliness, and depressed mood scores compared to healthy peers. However, the precise reasons are somewhat unclear (Forgeron et al., 2011b). It is possible that having a negative self-image contributes to feeling unequal to others in a group and to decreased participation in sport and leisure activities. Even when these adolescents spend time with friends, they may feel different and unequal to their friends, which can disrupt the establishment of close friendships.

### Close friends

The majority of the research on close friendships and pain has been conducted with adolescent populations. This is understandable, as the prevalence of chronic pain tends to increase around or after puberty (King et al., 2011; Stanford et al., 2008). Adolescents with chronic pain have identified close friends as being both helpful and unhelpful in coping with chronic pain (Forgeron and McGrath, 2008). In a recent study, Forgeron and colleagues (2011b) found that adolescents with chronic pain rated narrative vignettes depicting a non-supportive social interaction between an adolescent with chronic pain and a close friend as more unsupportive compared to healthy peers. Although adolescents with chronic pain had higher rates of loneliness and depressed mood and lower self-esteem, scores on these measures did not contribute to the variance

explained in the interpretation of non-supportive social situations. Adolescents with chronic pain may have a heightened sensitivity to negative social situations, as these situations may have the potential to negatively impact their pain experience. According to the SCM, adolescents with chronic pain who have experienced unsupportive social situations involving their friends may try to avoid these situations to avoid feeling uncared for by their friends. These situations may then be interpreted with heightened sensitivity in the future, due to the possibility of experiencing negative consequences. In other studies, adolescents with chronic pain described their friends as unable to understand their pain condition, alluding to the notion that their friends were unsupportive (Carter et al., 2002; Forgeron and McGrath, 2008). One of the reasons that friends might not fully understand an adolescent's pain condition is the unpredictable nature of pain. There are times when adolescents with chronic pain are able to socially engage much like their healthy peers and other times when pain interferes significantly with physical and social functioning. Additionally, as most chronic pain conditions are not visible, healthy friends may not always provide the level of support desired by the adolescent with chronic pain. Thus, adolescents with chronic pain may experience feelings of loneliness, even when they do engage with friends, if they feel they cannot fully share their pain experience with others.

Carter and colleagues (2002) reported that adolescents with chronic pain often describe 'sunny day friends' as friends who are only present when pain is not problematic. Interestingly, adolescents with chronic pain described some of their friends as having changed, as opposed to changing themselves. This finding points to a potential dichotomy between adolescents with chronic pain and their friends. Healthy friends may perceive the adolescent with chronic pain as the one who has changed. Not only does pain interfere with leisure and sport activities, but it can also contribute to disrupted sleep and irritability. One participant in a study by Sällfors and colleagues (2002) described classmates being shocked as she became more irritable when she was in pain. Thus, fatigue and irritability (a form of pain expression) may explain why some healthy friends only wish to interact with the adolescent with chronic pain when pain expression is minimal. Children and adolescents with chronic pain expressed difficulty when their friends did not believe them, and felt as though they were being blamed for their condition (Forgeron and McGrath, 2008; Sällfors et al., 2002).

Friends of children and adolescents with chronic pain continue to have friendship needs, regardless of whether the child or adolescent with chronic pain is able or willing to engage in various social activities. Healthy children and adolescents may develop additional friendships to buffer their own loneliness when their friend with chronic pain is not in school or unable to participate in social activities. It is not clear if or how friendships change over time when a child or adolescent has chronic pain. Healthy friends may be more understanding when the pain first begins but over time may need to find alternative friends to fill their own friendship needs.

Support from friends has a self-reported positive impact on social functioning (Carter et al., 2002; Forgeron and McGrath, 2008; Sällfors et al., 2002). Friends have been described as providing distraction, understanding, companionship (Carter et al., 2002; Forgeron and McGrath, 2008; Sällfors et al., 2002), and emotional and academic support to adolescents with chronic pain. Although close friends can provide positive support, it is unlikely that they provide support in every situation. In the narrative vignette study

described earlier (Forgeron et al., 2011b), adolescents with chronic pain and healthy controls listed alternative responses to the healthy character's response depicted in the vignettes. The responses were coded as inclusive/helpful or not inclusive/helpful. There were no differences between the two groups with respect to the number of inclusive/helpful alternatives that were listed across the 12 vignettes. However, adolescents with chronic pain endorsed significantly more inclusive/helpful alternatives when asked to describe what they would have done if they had been the healthy character in the vignette. Even when healthy peers know what might be supportive to a friend with chronic pain, they may not feel skilled or prepared to provide that support in all situations. Alternatively, adolescents with chronic pain may have expectations that are above and beyond what another adolescent is capable of providing.

There are several caveats that should accompany the research previously described. First, positive alternative behaviours were coded as supportive if they ensured the inclusion/help for the adolescent with chronic pain. It remains unclear, however, if providing such support would improve the social functioning of an adolescent with chronic pain. Being overly solicitous may result in less competent social functioning, as it may enforce the belief that the adolescent with chronic pain believes his or her needs have priority over others. Nevertheless, even if participation in social activities is not increased by supportive friendship behaviours, perceived support may help an adolescent with chronic pain feel valued as a friend. Additionally, close friends are reciprocal in nature, therefore it may be important to ensure that adolescents with chronic pain remain empathic to the needs of their healthy friends. Second, sex differences in friendships exist in typically developing children and adolescents. Specifically, male friendships are characterized by more physical presence and female friendships are characterized by more emotional sharing (Benenson and Christakos, 2003). Although the vignettes included both physical activity situations and emotional sharing situations, there were not sufficient numbers of both to analyse separately. It is unclear if there are differences in the types of situations perceived by adolescents with chronic pain as non-supportive based on their sex. There is no research that examines the types of support offered by a friend and the pain coping and social functioning of children and adolescents with chronic pain.

In contrast to their healthy friends, adolescents with chronic pain may develop a different perspective on how they view friendships, support, and their place within relationships as a result of their pain. Adolescents in several qualitative studies described pain as interrupting their ability to be 'normal' (Carter et al., 2002; Forgeron and McGrath 2008; Sällfors et al., 2002) and making them feel different from their 'normal' healthy friends. Adolescents who have not experienced chronic pain may not appreciate the challenges of living with a chronic condition. Chronic pain does not always have an identifiable cause and there are no diagnostic tests that confirm the existence of pain. Additionally, although most healthy children and adolescents have experienced some form of acute pain, these experiences would not prepare them with the knowledge and understanding that adolescents with chronic pain feel they need from their friends. Not only could this difference in perspective lead to misunderstandings, but the invisible nature of chronic pain can add to confusion for healthy friends who do not understand how functioning can vary so much in their friend with chronic pain (Forgeron and McGrath, 2008; Sällfors et al., 2002).

## Peers

Peer acceptance (unilateral liking/popularity) has been studied more extensively than close friendships in children and adolescents with chronic pain; however, results of studies completed to date have been inconclusive. Some researchers suggest there are no differences in peer acceptance of children and adolescents with chronic pain (Guite et al., 2000; Noll et al., 2008, 2010), whereas others suggest that there are differences (Kashikar-Zuck et al., 2007; Vanetta et al., 2008). Kashikar-Zuck and colleagues, using a classroom rating approach compared likeability ratings of adolescents with juvenile fibromyalgia with age-matched controls from the same class, found that peers rated the adolescent with juvenile fibromyalgia as less likeable than classmates (Kashikar-Zuck et al., 2007). However, Noll and colleagues using the same classroom rating approach did not find any differences in likeability between adolescents with juvenile arthritis and age-matched classmates (Noll et al., 2000). It remains uncertain which factors may contribute to the contrasting findings reported in these two studies.

One factor may be explained versus unexplained pain. Recurrent and ongoing pain from juvenile fibromyalgia is not as well understood compared to the pain from juvenile arthritis. In a hypothetical vignette study, 4th and 5th grade children in the US rated same age peers with both explained and unexplained abdominal pain as equally likeable as playmates (Guite et al., 2000). Older children and adolescents may perceive unexplained pain more negatively compared to younger children. Younger children may not have a biological understanding of illness and therefore do not make judgements based on the underlying aetiology of illness condition of a friend. Conversely, for older children and adolescents, the complexity of unexplained pain may not fit with their biological understanding of illness, which then contributes to judging children and adolescents with chronic pain as different than peers and hence less compatible.

Alternatively, peer likability of children or adolescents with unexplained chronic pain may not be related to age but instead related to the difference between actual versus hypothetical experiences of interacting with an adolescent with a chronic pain condition. In actual *in vivo* interactions with peers, there may be a negative iterative process between the pain behaviours expressed by the adolescent with chronic pain, the interpretation of these behaviours by peers, and further expression of pain that negatively impact peers' perception of the adolescent with unexplained recurrent or chronic pain.

There also are inherent limitations to the studies that compare peer relationships of children and adolescents with pain conditions with healthy peers (Kashikar-Zuck et al., 2007; Noll et al., 1996, 2000, 2007; Vannatta et al., 2008). The majority of the previously discussed studies examined perceptions of children and adolescents with various chronic pain conditions using a variety of sociometric measures. All researchers used classroom peers as the only measure of acceptance or likeability and did not examine other friendships the child or adolescent might have outside the classroom or school. Limiting research to classroom sociometric measures may be problematic when studying adolescents in junior high and high school, as class composition generally changes from class to class, and adolescents have increased opportunities to make friends in other settings. Most of these researchers also focused on quantity compared to the quality or characteristics of the friendship; therefore, it is

unclear whether being viewed as accepted by classmates translates into deeper friendships for children and adolescents with chronic pain. Finally, most of the researchers explored peer relationships for a wide age range (i.e. 8–18 years); this is problematic, as patterns of peer relationships change as children age. Therefore, the inclusion of both children and adolescents may not have provided the necessary power in these studies to find subgroup differences. Since there were some interactions between pain and age of the child or adolescent, the separation of these developmental groups may be especially important.

Some studies used standardized quantitative measures to examine peer relationships of children and adolescents with chronic pain compared to healthy children and adolescents (Noll et al., 2000, 2007; Vannatta et al., 2008). Although using standardized measures is advisable, these measures may not be robust for children with chronic illness, as they may lack construct validity for this population (e.g. Perrin et al., 1991). Adams and colleagues (2002) note that a lack of normative data exists for some measures and clinical measures of child social functioning are generally designed to differentiate psychopathology versus a continuum of function. For example, if a child with chronic illness is not picked as often for a sport team, does this truly represent classmates' negative perception of the child or is this a reflection of classmates' recognition of the child's limitations? These measures also may not capture the true sense of perception of their peer relationships by the child or adolescent with a chronic pain condition.

Several researchers report that children and adolescents with chronic pain are subjected to more peer victimization than healthy children (Greco et al., 2007; Natvig et al., 2001). However, no causal link has been established between peer victimization and recurrent or chronic pain. Children and adolescents who experience recurrent or chronic pain may be viewed by their peers as more vulnerable than healthy children and therefore be preferred targets for more frequent bullying. The stress that results following peer victimization may subsequently increase a child's or adolescent's pain from a manageable to an unmanageable level. Relational victimization (i.e. aggression that impacts one's social status) can result in children and adolescents with chronic pain feeling stigmatized for having pain. In a focus group study exploring the self-identified needs of adolescents with chronic pain, one male participant described the experience of being asked personal questions from a non-friend peer and then subjected to cursing when he ignored her questions (Forgeron and McGrath, 2008). There also may be sex differences in the types of victimization children and adolescents with chronic pain are exposed to. For example, boys with abdominal pain who reported peer victimization experienced both overt and relational forms of victimization whereas girls with abdominal pain only reported relational forms of victimization (Greco et al., 2007). The significance of this sex difference regarding victimization is unclear, but relational victimization may be more difficult to recognize. As already noted, no research describes the consequences of having fewer friends compared to typically developing peers. However, given that positive friendships have been found to buffer the negative effects of peer victimization (Hodges et al., 1999) it is essential to understand the relationship between chronic pain and the actual number of close friends as having fewer friends suggests that they may be more impacted by peer victimization actions.

## School functioning

School is central to the life of children and adolescents. Not only is school essential for academic learning, it also provides opportunities for children and adolescents to engage in social activities and relationships. Being exposed to different types of social relationships helps children develop social knowledge and practise a broad range of social skills, thereby leading to competent social functioning. However, school can also be a place of stigma and discrimination for children and adolescents with chronic pain. Chronic pain can negatively impact on academic performance and change relationships with teachers.

## Academic achievement

Pain can negatively impact school attendance, which can contribute to academic and social sequelae. Youth with chronic pain may miss 1 to 5 days of school per month (Konijnenberg et al., 2005; Logan et al., 2008; Roth-Isigkeit et al., 2005); 20% of children and adolescents with chronic pain recruited from a pain clinic, can be absent from school more than 50% of the time (Logan et al., 2008) and 14% may be totally absent from school (Konijnenberg et al., 2005). However, absences alone do not account for all of the academic challenges faced by children and adolescents with chronic pain.

Ho and colleagues (2008) found that children and adolescents with chronic pain did not differ on standard cognitive tests in comparison to healthy children and adolescents, suggesting that intelligence is not negatively affected by the presence of a chronic pain condition. What may be affected, however, is an adolescent's ability to sustain the necessary focus and concentration to study and reach his or her academic potential. Logan and colleagues (2008) found 44.3% of adolescents with chronic pain and their parents reported a decrease in their grades since the onset of pain. The decline in grades ranged from one to four levels (i.e. a four-level change would mean that a student who generally achieves 'As' would now mostly achieve 'Cs'). Adolescent participants in other studies have reiterated experiencing difficulty in their academic ability due to chronic pain (Forgeron and McGrath, 2008).

Chronic pain can have a significant negative effect on academic achievement, and perhaps academic self-efficacy. Bandura (1993) suggests that a student's perceived self-efficacy in terms of ability to manage their learning and develop proficiency in academic activities affects motivation, goals, and academic success. Chronic pain may change an adolescent's self-efficacy in the academic realm as a result of the decrease in grades that often accompanies chronic pain.

Logan and Curran (2005) note that teachers face many challenges when working with students experiencing chronic pain and subsequently need more information about chronic pain conditions from health care professionals, as well as guidance on how to manage pain symptoms and pain-related behaviours in school. In our experience, teachers indicate that they desired ongoing dialogue with health professionals in addition to receiving a formal letter informing them of the student's pain condition, similar to what has been supported by others (Logan and Curran, 2005).

Stress may add to school challenges for children and adolescents with chronic pain. Although both healthy children and children with recurrent abdominal pain experience more stress at school than outside of school, children with recurrent abdominal pain report greater daily stressors and a stronger association between

stressors and pain symptoms than healthy children (Walker et al., 2001). Pain has also been associated with unhappiness at school (van Dijk et al., 2008), but the specific causes of school unhappiness are not entirely clear. Classmates and teachers may not understand an adolescent's pain and thus do not make necessary allowances for challenges that may arise in the school setting (Forgeron and McGrath, 2008). Classmates are often confused when children and adolescents with chronic pain are able to participate in physical activities one day but not another (Sällfors et al., 2002). Additionally, teachers may question the validity of an adolescent's pain condition (Logan and Curran, 2005). For example, Logan and Curran (2005) examined teacher perceptions of students with chronic pain and found that some teachers were sceptical of the validity of these students' pain report based on the association between context factors and pain expression. Specifically, teachers were concerned that adolescents might use pain as an excuse (fake pain) to be excused from tests or to receive attention from peers. Thus, negative perceptions and reactions from others may be a factor contributing to inability to concentrate in the classroom, as well as overall school unhappiness in children and adolescents with chronic pain.

There is no evidence to suggest that students with pain fake their pain to reduce school assignments or to avoid tests and exams. Interestingly, there is evidence that parents are able to easily detect when their child is faking pain but have more difficulty detecting when their child or adolescent is suppressing pain (Larochette et al., 2006). Thus, teachers may actually under-detect pain in the classroom, especially if a child or adolescent is suppressing his or her pain expression to blend in with classmates. When a student with chronic pain encounters a teacher who gives the impression that he or she believes the student is 'faking' he or she may feel stigmatized by the school experience.

### Social context of school

When children and adolescents with chronic pain are absent from school, they are also absent from their primary social environment and risk falling behind in the social knowledge and exchanges that take place during the school day. Specifically, they may not be aware of the social events from previous days and the topic of conversation, which may contribute to feeling alone despite being among peers. Thus, the process of returning to school after a period of absence can be challenging because of the negative impact of their absence on academic skills and on their social knowledge.

Children and adolescents with chronic pain may feel singled out and different from their classmates (Forgeron and McGrath, 2008). This can be due to teachers and other students asking questions upon their return that make them feel unsupported and judged. These questions may include asking for reasons for their absences, details about their medical conditions, justification for academic or physical accommodations, and being outwardly teased by classmates. Additionally, in a study by Sällfors et al. (2002), adolescents have noted that it was often difficult to sit out of certain classes (i.e. physical education) and complete academic assignments while their classmates were having fun. Clearly, being separated from classmates would serve to highlight their pain condition and the differences between adolescents with a pain condition and their healthy peers. Although children and adolescents with pain conditions may not be able to participate in classes such as physical education, they may prefer to either take part in a modified version of the physical activity (e.g. walking rather than running, if possible)

or complete academic assignments elsewhere (e.g. the library or an empty classroom) so as to protect themselves from standing out from their healthy peers.

Adolescents describe feeling punished for their pain condition when teachers are unwilling to grant them academic accommodations (Forgeron and McGrath, 2008). These reactions (a response to their pain expression) may increase their stress and perhaps even their pain intensity (due to the relationship between stress and pain), which, in turn, affects their ability to attend school. However, when teachers modified academic requirements, adolescents with chronic pain reported feeling supported and perceived these accommodations as acknowledgement of their pain as real (Forgeron and McGrath, 2008).

Many schools have restrictions on participation in committees, sports, and special school events based on either school attendance or grades. Adolescents with chronic pain feel further punished when they are unable to participate in these extracurricular events. Having these restrictions waived for children and adolescents with chronic pain has a positive effect on how they feel in the social context of school, which then has a positive effect on how these students feel in the academic context. Collaboration and dialogue is necessary to obtain a waiver of these restrictions and to help teachers understand how their reaction to a student with chronic pain can either result in the student feeling supported or add to the student's stress.

## Recommendations

Although there are no intervention studies to date that identify the most useful strategies to help children and adolescents with chronic pain manage peer relationships and friendships, we propose intervention strategies that are informed by the research reviewed in this chapter.

### Clinical recommendations

Clinicians must recognize that chronic pain may present challenges to peer relationships and friendships. Children and adolescents may be reticent to speak negatively about their friends, as they acknowledge that many of their friends were supportive at times. Thus, ensuring a safe environment to discuss concerns is needed.

Improving peer perceptions of children and adolescents with chronic pain is important, as positive peer relationships have been positively correlated with more positive perceptions of social abilities of adolescents with chronic pain (Eccleston et al., 2008). Exploring situations in which peers and close friends have not been supportive may help the child or adolescent with chronic pain, as non-supportive situations tend to be the most troubling for this population and may lead to disengagement from friends. The clinician should work with the child or adolescent with chronic pain to determine an approach so the child or adolescent could take control of the situation. For example, they could practise the types of conversations that may occur with their friends and learn the types of actions that are helpful and non-helpful in conversations with friends. Helping a child or adolescent understand that some of their pain behaviours may be difficult for their friends to understand may also be needed. These discussions, along with activities such as role playing, may help the adolescent practise how to take control and advocate for their friendship needs. However, the adolescent with chronic pain must also understand that his or her needs should

be balanced with a willingness to listen to their friends' needs, as friendships are reciprocal. Taking control of these situations may improve friendship quality by not only securing the friendship needs of adolescents with chronic pain but also allowing friends to discuss their friendship needs when the adolescent with chronic pain disengages from activities.

Understanding one's pain condition has been linked to acceptance and engagement in treatment; therefore, pain education is often offered to children and adolescents with chronic pain to help them understand their condition. However, pain education targeted at helping the child or adolescent develop language to help explain their condition to others has not been developed. It is necessary for a child or adolescent to understand his or her pain condition in a way that they could translate to their friends to decrease the scepticism they encounter. Future research should attempt to develop and evaluate interventions that focus on developing appropriate language to describe pain to others.

Given the regularity that some adolescents with chronic pain are absent from school, their friends may not find their absences unusual. Children and adolescents who miss school due to pain may need to be proactive in contacting their friends to fill them in on the social activities of the day. This approach may help a child or adolescent with chronic pain who is absent from school regularly to remain informed of the social context and perhaps a feeling of belonging when they do go back to school. Technology such as webcams and real-time chatting over the Internet could be offered as helpful tools to allow children and adolescents with chronic pain to continue interacting with their peers remotely.

### School accommodations

Academic accommodations may help adolescents with chronic pain to view their teachers as taking a more positive attitude towards them and believing in their pain condition. Student perceptions of positive teacher regard have been linked to increases in academic values, achievement, and feelings of academic competency (Roeser and Eccles, 1998). Many of the adolescents in a study by Logan and colleagues (2008) had some form of accommodation in place; teachers rated students with more accommodations as being better adjusted to school compared to typical peers. Therefore, even when chronic pain negatively impacts academic performance the implementation of accommodations may help students perceive themselves as valued competent students.

The following academic accommodations have been identified as helpful either from clinical experience or the literature. First, regular communication between and among the health care professionals, school, and family is needed (Logan and Curran, 2005). Second, teachers are more apt to provide requested academic accommodations if the health professional provides these suggestions in writing (Forgeron and McGrath, 2008; Logan and Curran, 2005). Third, academic accommodations that offset the negative cognitive consequences of chronic pain need to be individualized, as not all patients require every accommodation. Such accommodations may include a combination of the following: (1) class notes (i.e. for missed work or to reduce motor demand when in class), (2) spacing out of projects and tests to allow for the increase length of time to complete tasks, and (3) decreased workload (i.e. the quality should be the same but amount may need to be reduced). Finally, in our clinical experience, having one teacher (or guidance counselor) to act as a student advocate within the school has been helpful.

This member of the teaching staff is someone the student can go to have issues resolved instead of having to negotiate with several teachers at once.

Some children and adolescents may require physical accommodations such as the ability to leave their desk and walk around, have a private place outside of class (e.g. guidance or nurse office) to use non-pharmacological pain-reducing strategies (e.g. relaxation exercises such as deep breathing and guided imagery), or the use of an elevator pass or access to water in class (i.e. especially for children or adolescents on certain medications). These physical accommodations are aimed at helping to reduce pain in the moment so that the child or adolescent is able to remain in the school even if he or she must miss a class. In our clinical experience, once a child or adolescent leaves school due to their pain it is unlikely that the student will return to school that day.

A formal request for the child or adolescent to be exempt from the attendance or grade requirements to participate in school social life is also important. When excluded from school social life due to their pain condition, children and adolescents may feel as though they are being punished as a result of their condition. The more excluded socially, the more likely they are to experience loneliness, and other associated psychosocial sequelae (e.g. anxiety or depression). Children and adolescents with chronic pain may benefit from health professionals having a discussion with teachers regarding the best ways to communicate with a student challenged by chronic pain. Children and adolescents do not want to stand out and appear different from their peers; therefore, it is important to remind school personnel to keep conversations about pain and health confidential. A template of a school letter, developed and used at our clinic (IWK Health Centre, Halifax, Nova Scotia—where the first author was the clinical nurse specialist) is part of the online supplement of this chapter. An important component is a basic explanation of the physiology of chronic pain that may help teachers to reinforce the legitimacy of chronic pain to school personnel. We encourage other clinicians to use or modify this letter if they feel it would be useful in advocating for children and adolescents with chronic pain.

### Research recommendations

There is limited research on the social consequences of chronic pain for children and adolescents. Little is known about the processes of how peer relationships or friendships impact the chronic pain experience and functioning of children and adolescents, or the processes through which pain impacts friendships. It appears that withdrawal from activities and school absences are important factors but further research examining the relationship between pain expression and pain interpretation are needed to understand the impact of these factors. To date, most of the research focuses on peer relationships and needs to expand to include close friendships. Additionally, examining the relationships of adolescents separately from children would allow developmental differences to be revealed. Studies are also needed that account for differences between male and female friendships. Finally, intervention studies to determine the best ways to maintain and strengthen close friendships are needed.

Although chronic pain may negatively affect subjective reports of academic performance (Dick and Pillai-Riddell, 2010), the exact processes remain elusive. Pain may negatively impact concentration and focus. However, negative academic performance may also be related to other pain related factors such as sleep disturbances.

Changes in social relationships in the school setting (both with peers and teachers) may contribute to a decline in overall school performance and school absence may intensify or be a consequence of these factors. Research is needed to examine the processes that interfere with specific aspects of school performance (academic performance, social relationships, restrictions on school involvement) along with designing and testing strategies that improve overall school performance.

## Conclusion

A clear understanding of the social and school functioning of children and adolescents with chronic pain is an essential part of their clinical care. We have suggested strategies on to support improved social functioning and school performance-based current research. However, more research is needed to understand the processes underlying social functioning and school performance so that more specific interventions can be designed and implemented, thereby allowing children and adolescents challenged by chronic pain to be as successful as possible in the academic and social spheres.

### Case example

Jill is a 16-year-old girl who developed widespread body pain at the end of the school year and her pain intensity progressively increased over the summer months. She has seen several specialists and all her diagnostic tests come back within normal limits. She rates her pain as 7 out of 10 most days with exacerbations up to 10 out of 10 at least once a week. The pain is keeping her from sleeping well; she finds it hard to fall asleep and wakes frequently thought the night because of pain. She started 10th grade 2 months ago, which meant a change in schools. She is missing about 2 to 3 days of school a week. Her classmates from last year are attending the same school but most are not in her classes.

In grade 9 Jill was on the volleyball team and achieved straight As. Her parents are supportive but wonder why the doctors cannot find anything wrong with Jill. Jill used to go out with her friends regularly and is described by her parents as being popular. However, since developing the widespread pain, she has been home much more, hardly goes out with her friends on the weekend, did not try out for the volleyball team, and her marks are now in the Bs. Jill reports that getting up from her seat and going for a walk is helpful when her pain becomes unbearable in class, but some of her teachers do not allow her to leave the classroom citing that she has missed so much time that she cannot afford to miss any more instruction. In private Jill mentions to you that she does not like to go out as she may have pain when she is out socializing. She also mentions that her friends called a lot when she first became ill but have stopped calling her.

Is Jill experiencing school avoidance?

What would you suggest from an academic perspective?

What would you suggest from a social perspective in terms of school?

Why do you think Jill's friends are no longer contacting her?

## CHAPTER 14

# The effects of sex and gender on child and adolescent pain

Erin C. Moon and Anita M. Unruh

### Summary

As women enter adulthood, they are at an increased risk for a number of clinical pain conditions and show higher experimental pain sensitivity relative to men (e.g. Fillingim et al., 2009). The feminine gender role encourages the expression of pain in both children and adults whereas the masculine gender role encourages stoicism in response to pain (e.g. Robinson et al., 2001; Zeman and Garber, 1996). The earlier work of Unruh (1996), Berkeley (1992, 1997), and LeResche (1997), demonstrated that sex and gender shaped the experience of pain and a subsequent body of research has continued to articulate their influence.

Before examining this literature, it is important to distinguish between the terms sex and gender. Sex usually refers to biological aspects and gender to the social or cultural dimensions of being male or female (Owen Blakemore et al., 2009). The World Health Organization defines sex as 'the biological and physiological characteristics that define men and women' and gender as 'the socially constructed roles, behaviours, activities, and attributes that a given society considers appropriate for men and women' (World Health Organization, n.d., para. 1).

This chapter will begin with a brief overview of sex and gender differences in adult pain to provide a context for then examining sex and gender differences in child and adolescent pain. The chapter will continue with a discussion of the biological, family, and socio-cultural factors thought to contribute to sex and gender differences in child and adolescent pain.

### Sex and gender differences in adult pain

Much of the early research on sex differences in adult pain focused on experimental paradigms. A 1998 meta-analysis of these studies concluded that women were more likely to report lower pain threshold and tolerance than men, with effect sizes of  $d = 0.55$  for threshold and  $d = 0.57$  for tolerance (Riley et al., 1998). In an updated meta-analysis, Fillingim et al. (2009) concluded that there are reliable sex differences in pressure and electrical pain, with women reporting greater sensitivity than men. The largest study to date to assess sex differences in pain threshold using multiple experimental modalities found that women have significantly lower pain thresholds than men (Rolke et al., 2006).

In epidemiological studies worldwide, Fillingim et al. (2009) reported that neuropathic pain, chronic musculoskeletal pain, abdominal pain, headache, and migraine were more prevalent in women compared to men, and women had pain in more anatomical sites. Similarly, Tsang et al. (2008), in a study spanning 17 countries, found that women reported a higher prevalence of common chronic pain conditions.

Though sex differences are evident in experimental and epidemiological studies, in adult clinical pain samples they are equivocal. In a study of pain ratings in five samples of patients at chronic pain clinics, women were slightly more likely to give higher pain severity ratings than men (Robinson et al., 1998). Other studies have not reported sex differences (e.g. arthritis: Lander et al., 1990; temporomandibular pain: Bush et al., 1993; Wilson et al., 1994).

Findings on adult sex differences in medical procedure and postoperative pain are also inconsistent. In a study of needle procedures, women reported higher pain intensity (Ring et al., 2009). In a review of 15 studies of postoperative pain, Fillingim and colleagues (2009) concluded that women gave higher pain intensity ratings but noted that conflicting outcomes were also reported in some studies.

Men and women may cope differently with pain. The most robust findings are that women use more social support to cope with pain and a greater number of pain coping strategies compared to men (Unruh, 1997). Although not all studies find sex differences in catastrophizing (e.g. Unruh et al., 1999), there is evidence that women do catastrophize about pain more than men (Edwards et al., 2004; Jensen et al., 1994; Keefe et al., 2000).

Fewer studies have considered the impact of gender on adult pain. Existing studies show that higher scores on measures of masculine gender role stress increase systolic blood pressure reactivity to pain (indicating stress; e.g. Lash et al. 1990). Higher masculinity scores have also predicted higher pain tolerance and lower pain ratings (Otto and Dougher, 1985; Thorn et al., 2004).

There is no critical age marking the onset of sex and gender differences in adult pain. A number of studies suggest that the socialization mechanisms that shape gender role expectations of pain begin in childhood and that puberty is the biological catalyst for the onset of the physiological mechanisms that contribute to sex differences in pain (Unruh and Campbell, 1999).

## Sex differences in child and adolescent pain

In 1999, Unruh and Campbell concluded that sex differences in studies of experimental pain in childhood and adolescence were not consistent but when they occurred, they were in the same direction as in adult studies. Girls generally reported similar or lower pain thresholds and tolerance compared to boys. The experimental studies of child and adolescent pain published since 1999 are summarized in Tables 14.1 and 14.2.

Two of these experimental studies used quantitative sensory testing (QST), a battery of somatosensory processing tests that provide reliable and valid measures of sensory thresholds in children (Meier et al., 2001), with different outcomes. Walker et al. (2009) used QST in a study of the long-term impact of early pain and injury on sensory perception. There were no sex differences in mechanical (pressure) detection thresholds between children born premature (and now 11 years of age) and a control group of children born full-term. Nevertheless, in the control group, boys were significantly more sensitive to heat and cold detection than girls. In contrast, with a healthy sample of 6- to 16-year-olds, Blankenburg and colleagues (2010) found that girls were more sensitive to heat and cold detection, as well as heat and cold pain stimuli, than boys. The wider age

range of the participants in the Blankenburg et al. study may help account for these divergent findings.

In a sample of 244 children, Lu and colleagues (2005) found no sex differences in heat pain tolerance, but girls had a significantly

**Table 14.2** Summary of recent child and adolescent cold pressor task studies reporting on sex differences

Authors, year	Age range	Sex difference findings
Chambers et al., 2002	8–12 years	Pain intensity: no differences
		Pain affect: no differences
		Pain tolerance: no differences
		Heart rate: no differences
		Facial activity: boys > girls
Coldwell et al., 2002	8–11 years	Pain intensity: no differences (sex not predictor in regression)
Evans et al. 2008	8–18 years	Pain intensity: no differences
Goodman and McGrath, 2003	10–14 years	Pain intensity: no differences
		Pain tolerance: no differences
		Pain threshold: no differences
		Facial activity: no differences
Jaaniste et al., 2007	7–12 years	Pain intensity: no differences
		Pain tolerance: no differences
Larochette et al., 2006	8–12 years	Facial activity: no differences
Moon et al., 2008	4–12 years	Pain intensity: no differences
		Heart rate: no differences
		Facial activity: no differences
Myers et al., 2006	8–18 years	Pain intensity: more boys than girls in 'low pain' group
		Pain affect: no differences
		Pain tolerance: no differences
Pepino and Mennella, 2005	5–10 years	Pain intensity: no differences
		Pain tolerance: no differences
Piira et al., 2002	7–14 years	Pain tolerance: no differences (age by sex interaction)
Piira et al., 2006	7–14 years	Pain intensity: no differences
		Pain tolerance: no differences
Trapanotto et al., 2008	8–12 years	Pain intensity: no differences
		Pain affect: no differences
		Pain tolerance: no differences
Tsao et al., 2002	8–10 years	Pain intensity: no differences
		Pain tolerance: no differences
Tsao et al., 2006a	8–18 years	Pain intensity: no differences
Tsao et al., 2006b	8–18 years	Pain intensity: no differences
Tsao et al., 2004	8–18 years	Pain intensity: more boys than girls in 'low-pain' group

**Table 14.1** Summary of recent child and adolescent experimental pain studies (paradigms other than cold pressor task) reporting on sex differences

Authors, year	Age range	Sex difference findings
Quantitative sensory testing		
Walker et al., 2009	11 years	Mechanical detection threshold: no differences
		Heat detection threshold: in control group, boys more sensitive
		Cold detection threshold: in control group, boys more sensitive
Blankenburg et al., 2010	6–16 years	Mechanical detection threshold: no differences
		Heat detection threshold: girls more sensitive
		Cold detection threshold: girls more sensitive
		Mechanical pain threshold: no differences
		Heat pain threshold: girls more sensitive
		Cold pain threshold: girls more sensitive
Pressure pain		
Lu et al., 2005	8–18 years	Pain tolerance: boys > girls
Lu et al., 2007	8–18 years	Pain intensity: no differences
		Pain unpleasantness: no differences
Heat pain		
Lu et al., 2005	8–18 years	Pain tolerance: no differences
Lu et al., 2007	8–18 years	Pain intensity: no differences Pain unpleasantness: no differences

lower pressure pain tolerance than boys. A mediation analysis indicated that this sex difference was due to a higher pre-trial heart rate in girls (an indication of autonomic arousal). With the same sample of children, Lu et al. (2007) reported no sex differences in pressure or heat pain intensity or pain unpleasantness.

Since the review by Unruh and Campbell (1999), 16 studies of cold pressor pain in children and adolescents have examined sex differences (see Table 14.2). With a few exceptions, most of these studies do not identify sex differences in pain intensity, pain tolerance, pain affect, or facial response to pain.

Girls are at an increased risk of chronic pain. Based on data from population-based studies conducted in America (Stewart et al., 1991) and Germany (Kroner-Herwig et al., 2007), Fillingim et al. (2009) concluded that while boys have an earlier onset of both migraine and non-migraine headache, as adolescence approaches, incidence and prevalence rises more quickly in girls. Sex differences in the prevalence of child musculoskeletal pain are not as clear. For example, a Finnish study (Mikkelsen et al., 1997) indicated an increased prevalence of chest and upper back pain in girls whereas a nationwide study of musculoskeletal pain in Swedish students (Brun Sundblad et al., 2007) did not detect sex differences. In this Swedish study, girls were twice as likely to have weekly abdominal pain as boys. Other epidemiological studies of child abdominal pain support the increased prevalence of abdominal pain in girls (Kristjansdottir, 1996; Oh et al., 2004; Ramchandani et al., 2005; Stanford et al., 2008). In a study of Canadian adolescents, girls had higher rates of all types of pain (e.g. headaches, stomach aches, and backaches) than boys (Stanford et al. 2008) and in a European study, girls also reported more frequent chronic pain (Huguet and Miró, 2008).

Sex differences in clinical child pain have been explored in various studies but have not yet been the subject of systematic review. In two clinical studies, girls reported higher current pain (Keogh and Eccleston, 2006) and more continuing pain and utilization of health care services (Martin et al., 2007). In a sample of adolescent cancer patients, Hechler and colleagues (2009) found that girls reported higher pain intensity in the past week and month, but boys and girls were similar in present pain intensity ratings. In two other studies, present pain intensity ratings were comparable in girls and boys aged 8 to 18 years (Kaczynski et al., 2009; Lynch et al., 2007).

Otherwise healthy children frequently endure pain from medical procedures such as immunizations and blood draws. Unruh and Campbell (1999) concluded that findings on sex differences in children's needle pain were inconsistent. Since 1999, evidence continues to be mixed. Five recent studies that compared boys' and girls' immunization and venepuncture pain found no differences (Caprilli et al., 2007; Cohen et al., 2000, 2004; Goodenough et al., 1999a; Kleiber et al., 2007). In contrast, Chambers and colleagues (1999) found that girls aged 5 to 12 years gave higher pain intensity ratings following venepuncture than boys. Similarly, sex differences were reported with older children (11–17 years; von Baeyer et al., 2009) and younger children (4–6 years; Sparks 2001) undergoing immunizations. In another study of venepuncture pain, Goodenough et al. (1999b) discovered that girls gave significantly higher pain unpleasantness ratings than boys from the age of 8 years onwards. These authors suggested that boys over the age of 8 years may be increasingly influenced by gender role expectations that boys should be stoic about pain.

Data on sex differences in child postoperative pain have not been systematically reviewed. The available evidence suggests that

similar to research with adults, sex differences in child postoperative pain are not clear. In one study, conducted with adolescents and young adults aged 12 to 20 years who had undergone elective surgery, girls gave higher pain intensity ratings than boys (Gillies et al., 1999). In addition, more girls in this study requested pain medication than boys in the first 24 hours after surgery. Another study, of children aged 5 to 13 years who had undergone minor surgery, found no sex differences in children's self-reports or parents' and nurses' reports of child pain intensity (Chambers et al., 2005). Similarly, in a study of children and young adults aged 8 to 21 years who had spinal fusion surgery, girls and boys gave similar postoperative pain intensity ratings and displayed similar levels of pain behaviour (Kotzer, 2000).

Regarding sex differences in coping with pain, data collected with child and adolescent samples parallels the findings from adult samples (Unruh and Campbell, 1999). Like women, girls aged 8 to 18 years use more social support in response to pain than boys (Keogh and Eccleston, 2006; Lynch et al., 2007). Boys in this age group use more behavioural distraction (e.g. doing something enjoyable to take their mind off pain; Lynch et al., 2007; Reid et al., 1998). The finding that boys are more likely than girls to distract themselves from pain has been interpreted as a way for boys to minimize pain and thereby act in accordance with the male gender role (Reid et al., 1998). Similar to studies in the adult literature, some studies with children and adolescents have not found sex differences in catastrophizing (Lynch et al., 2007; Reid et al., 1998) whereas other studies report that adolescent girls are more likely than boys to catastrophize in response to pain (Keogh and Eccleston, 2006).

## Gender differences in child and adolescent pain

The impact of gender on child pain outcomes has not been extensively studied but existing research suggests that masculinity may have an impact on some pain outcomes. Myers and colleagues (2006) measured the relationship between self-reported gender-stereotyped personality traits and pain ratings in children aged 8 to 18 years using the Child Sex Role Inventory (CSRI; Boldizar, 1991). Children underwent three pain tasks: pressure, cold, and thermal. Masculinity scores for boys were unrelated to pain tolerance on all three tasks but significantly inversely related to heat pain intensity and pain affect ratings. For boys and girls aged 14 to 18 years, higher masculinity relative to femininity scores predicted lower cold and heat pain ratings. Surprisingly, for boys and girls aged 8 to 13 years, higher masculinity relative to femininity scores predicted higher cold pain ratings.

In a second study using the CSRI, Moon (2010) examined the relationship between parents' ratings of their children's gender-stereotyped personality traits and cold pressor pain outcomes in children aged 8 to 12 years. Similar to the findings of Myers and colleagues (2006), child gender was not associated with cold pressor pain intensity, pain affect, pain tolerance, or pain complaints. Nevertheless, for children under the age of 13 years, Myers and colleagues found that higher femininity, relative to masculinity, was predictive of lower cold pressor pain intensity ratings. They interpreted these findings to mean that responses to cold pressor pain that are in keeping with gender-role stereotypes (i.e. higher masculinity being associated with lower pain ratings) may only emerge

after the age of 13 years. The findings of the study by Moon are in keeping with this interpretation.

## Factors that contribute to sex and gender differences in child and adolescent pain

In order to better understand sex and gender differences in pain, researchers have begun to consider the relative contributions and interactions of biological, family, and sociocultural factors.

### Biological factors

Sex hormones (mainly oestradiol, progesterone, and testosterone) play a role in men's and women's responses to experimental pain (e.g. Fillingim and Edwards, 2001; Riley et al., 1999) and have an impact on pain across the menstrual cycle (Unruh, 1996). Furthermore, sex differences in some pain conditions such as migraine headaches (Stewart et al., 1992) and temporomandibular disorders (LeResche, 1997) emerge only after puberty. There are also sex and hormonally determined differences in neuroactive substances such as gamma-aminobutyric acid, opioid and non-opioid analgesia, nerve growth factor (involved in pain perception), and the sympathetic nervous system that may help explain sex differences in experimental pain (Berkley, 1997).

Rodent models have been used to reduce the influence of socio-cultural variables inherent in studies of human sex differences in pain. Findings of this animal research have led to the generally-held conclusion that female rodents have a lower pain threshold (Hurley and Adams, 2008). Nevertheless, in a review of the literature on sex differences in both human and animal pain, Hurley and Adams noted that the animal models with the most clinical relevance for human pain (e.g. the Brennan et al. model of post-incisional pain in rodents; Brennan et al., 1996) have not uncovered significant differences between male and female animals.

Some researchers have used brain imaging techniques such as positron emission tomography to study sex differences in human response to pain. Women have shown greater regional brain activation of the thalamus, contralateral prefrontal cortex, and contralateral insula than men following painful thermal stimulation (Paulson et al., 1998); however, in another study, men had greater regional brain activation (Derbyshire et al., 2002). No significant difference in brain activation has been reported using functional magnetic resonance imaging following thermal pain (Moulton et al., 2006). At present, it is premature to conclude that there are sex differences in brain activation in response to pain, and no studies have included child or adolescent samples.

### Family factors

Parental behaviour has a powerful effect on child pain (Chambers et al., 2003; see also Birnie et al., Chapter 12, this volume). A handful of studies support the hypothesis that sex differences in child pain may be partly explained by familial socialization histories. These studies provide evidence that the expression of pain in girls is encouraged whereas the expression of pain in boys is discouraged by neutral or negative parental reactions (e.g. Kankkunen et al., 2003; Schechter et al., 1991; Walker et al., 1995).

According to the operant model of chronic pain (Fordyce, 1976), receiving attention from others about pain reinforces pain expression. Applying this model to child pain, Zeman and Shipman

(1996) suggested that parents may teach their children to behave in accordance with gender-role stereotypes for pain by giving their daughters more attention when they express pain compared to their sons. This position was supported by an experimental pain study with 8- to 16-year-old children in which parents tended to use more attention with their daughters and more distraction with their sons (Walker et al., 2006). These findings were not replicated in a more recent experimental pain study with 8- to 12-year-olds (Moon et al., 2011).

Until very recently, there have been few studies comparing and contrasting the socialization influence of mothers and fathers on child pain, but those that exist point to the importance of comparing these parental roles. Kangaroo care (providing skin-to-skin care by the parent holding a nappy-clad infant against the bare chest) has a significant impact on reducing an infant's response to painful procedures (Johnston et al., 2011). Johnston and colleagues (2011) have shown that this effect is marginally but significantly stronger for the mother than the father. (See Johnston and Campbell-Yeo, Chapter 58, this volume, for further discussion of mother care pain interventions.) Moon (2010) found that higher femininity scores, relative to masculinity scores, were associated with fewer pain complaints when girls underwent a cold pressor task with their fathers present, but not with their mothers present. In an intriguing study of the relationship between parental catastrophizing and pain intensity and disability in a children's pain clinic, Hechler et al. (2011) found that maternal, not paternal, catastrophizing was related to child pain intensity. Surprisingly, in this study, child disability was not significantly related to maternal or paternal catastrophizing. In another recent study, parental catastrophizing and child pain intensity were associated with the perceived threat inherent in the child's pain and the parent's need to control the child's pain, with the relationship stronger for mothers than fathers (Caes et al., 2012). Mothers have reported more use of non-pharmacological methods than fathers to manage pain in their children (Gorodzinsky et al. 2011). Future studies in this domain will be important in determining the complex relationship between familial socialization processes and gender differences in child and adolescent pain.

### Sociocultural factors

Research indicates that social roles support or permit pain expression for women but discourage it for men. Robinson and colleagues (2001) found that men and women expected men to have a higher level of pain endurance and a lower level of pain sensitivity than women. Pool et al. (2007) also reported that men and women believed that the ideal man should tolerate more pain than the ideal woman. Results from cross-cultural research indicate that such gender-role expectations are not unique to North American samples (e.g. Nayak et al., 2000; see also Clemente, Chapter 11, this volume).

Gender-role expectations for pain expression in children and adolescents have not been studied in detail. Still, a number of studies suggest that children, like adults, may behave according to gender-role expectations that encourage girls and discourage boys from expressing pain. In a widely cited early paper, Mechanic (1964) found that boys were significantly more likely to report that they were not afraid of getting hurt and that they did not pay attention to pain. Zeman and Garber (1996) found that girls reported they would be significantly more likely than boys to express pain in response to common pains. Girls were also more likely than boys to report that other people would understand and accept

their expressions of pain. These findings were echoed in a qualitative study of Canadian adolescents (Hatchette et al., 2008). Girls reported feeling free to discuss their pain with peers whereas boys reported being reluctant to express their pain to peers.

Gender-stereotyped beliefs about pain help explain findings that girls (Keogh and Eccleston, 2006; Lynch et al., 2007) and women (Unruh et al., 1999) are more likely to seek social support when they experience pain and that women show increased health care utilization for pain compared to men (e.g. Chang et al., 2006; Gibbs et al., 2003). Robinson and colleagues (2001) suggested that there may be a greater response cost involved when men report their pain because men are expected to be stoic in response to pain. Acting in a way that is incongruent with this expectation may cause men anxiety and embarrassment. It is possible that the pattern of observed adult sex differences in experimental but not clinical pain settings may be because the relatively mild experimental pain makes it easier for men to conform to male gender-role expectations (Myers et al., 2003). Clinical pain that is intense enough for men to seek medical treatment may override the desire to conform to the stereotypical male gender role.

There has been substantial criticism that pain in women is more likely to be interpreted as a psychological problem (e.g. Hoffmann and Tarzian, 2001; Unruh, 1996) but this issue has not been examined in studies of child or adolescent pain. The greater willingness of girls to express their pain to others may increase this risk.

## Clinical implications of sex and gender

The ways in which sex and gender may be manifested in children and adolescents in a pain clinic are illustrated in the following three case scenarios. The cases have been modified but reflect issues that have been clinically presented.

### Case example: Matthew

Matthew was 17 when he came to the pain clinic with his mother. He seemed to be coping well with his pain and was generally disinterested in treatment. His mother was more concerned about his pain than he was. Nevertheless, when he was later seen by the school guidance counsellor for behaviour problems at school, it was apparent that Matthew was extremely distressed by his severe pain and did not know what to do with his anger and frustration about it.

### Case example: Sonia

At 15, Sonia was seen by an orthopaedic surgeon for widespread pain that had originated 1 year earlier with back pain. As the imaging results were all negative, the surgeon told Sonia's parents that there was nothing wrong with Sonia. He told Sonia that if she found a nice boyfriend she would get better. By the time Sonia was seen at the pain clinic she had missed 8 months of school due to severe pain. As non-steroidal anti-inflammatory drugs (NSAIDs) had been ineffective in the past, and her sleep was poor, Sonia was started on gabapentin and amitriptyline. The psychologist saw her for pain-specific cognitive-behavioural therapy. A very slow pacing programme was initiated. Over the

next 4 years, Sonia progressed from no attendance at school to full attendance. By 5 years, she was pain-free and off pain medications. Sonia had many friends but in fact no boyfriend during these 5 years.

### Case example: Maggie

Maggie was 14 and had a long history of abdominal pain, but not menstrual cramps or menstrual pain. She was referred to the pain clinic from gastroenterology. Maggie was started on gabapentin and amitriptyline following an unsuccessful trial of NSAIDs. At a follow-up assessment, it was observed that Maggie's abdominal pain increased about the time of her menses. When NSAIDs were added to her regimen for the several days before its onset, her ongoing abdominal pain and its flare at menses improved.

These cases illustrate the way in which sex and gender may interact with pain in the clinical setting. Mathew hid his pain and his emotional reaction to it under a stoic demeanour. Clinicians initially interpreted his reticence to engage clinically as disinterest in treatment. Sonia's pain was interpreted as a social and probably psychological problem when there was no physical finding to point to a cause. Maggie's abdominal pain was due to other issues than menstruation, but her menstrual cycle produced flares that changed treatment needs. For clinicians, it is important to consider that gender role expectations may shape the way in which a child or adolescent will communicate about their pain, as well as their own perceptions of this communication. Similarly, biological factors may intersect with gender and affect pain in clinical settings, particularly after puberty.

## Recommendations for future research

Sex and gender differences are not usually the focus of pain research. Instead, sex is typically included as a demographic variable that may or may not be examined and reported. As noted by Unruh (1996), the results of studies that do not identify sex as a variable of primary interest *a priori* must be interpreted with caution because the power of these studies to detect sex differences is unclear. Pain researchers need to look beyond descriptive sex differences to examine how the psychosocial variable of gender affects child and adult pain responses. To date, only a handful of studies have examined gender differences in child and adult pain. This area is in great need of expansion. Fathers need to be included in research on sex and gender differences in child pain. With the exception of a few studies, fathers tend to be overlooked. In fact, 91% of child health psychology studies (including child pain), published from 1996 to 2003, involved only mothers or collapsed data from both parents (Phares et al., 2005). Particularly in research about sex and gender, the impact of parent gender on socialization cannot be ignored without compromising the meaningfulness of outcomes.

## Conclusion

Although the study of sex differences in child pain is not as advanced as the adult pain literature, evidence for sex differences in child and adolescent pain has accumulated in the past decade. Studies of sex differences in children's responses to experimentally

induced pain have largely focused on the cold pressor pain paradigm and have generally not uncovered sex differences. In contrast, epidemiological data indicate that girls are at an increased risk of a number of chronic pain conditions. Findings from child clinical pain studies are inconsistent, but generally suggest that boys and girls give comparable pain ratings. Findings from recent studies of needle pain are mixed but indicate that girls may give higher pain affect ratings. Postoperative pain findings are equivocal, with some studies indicating greater pain intensity in girls and others reporting no sex differences. Findings on sex differences in child pain coping strategies are remarkably similar to findings with adults. Girls appear to seek more social support for pain whereas boys are more likely to engage in distraction. Similar to the adult literature, some data also suggest that girls may be more likely than boys to catastrophize in response to pain. Although gender influences adult pain responses, the study of gender differences in child pain has not been extensive. Researchers have only just begun to delineate the impact of biological, family, and sociocultural factors on sex and gender differences in pain. Inconsistent findings highlight the need for further expansion of this field.

## Acknowledgements

The authors acknowledge the assistance of Dr Paula Forgeron, University of Ottawa, in the preparation of the case examples.

## CHAPTER 15

# Sleep and pain in children and adolescents

Bruce D. Dick, Penny Corkum, Manisha Witmans, and Christine T. Chambers

### Summary

Ongoing pain is a problem that affects a large number of children and adolescents. It has been well documented that recurrent and chronic pain are associated with many difficulties related to both physical and psychological function. A major difficulty that many young people with chronic or recurrent pain experience is disrupted sleep. Sleep problems have been reported to exist in as many as 50% or more of children with chronic illnesses (Owens, 2007). In many cases, pain is reported by the sufferers to cause sleep fragmentation as well as significant difficulties with delayed sleep onset. As well, there is increasing evidence that disrupted sleep is associated with increased pain. Both pain and sleep disruption further complicate the patient's overall clinical picture by making it more difficult for children and teens to cope with health problems and associated difficulties. Further, there is evidence that childhood sleep problems can have important negative effects on adult sleep patterns and, thereby, influence health status later in life (Fricke-Oerkemann et al., 2007; Sivertsen et al., 2009). This chapter will address the prevalence, importance, and consequences of sleep problems in children and adolescents with pain. First, the prevalence and possible relationship between pain and sleep will be discussed. Next, we will highlight the assessment of sleep with a specific focus on assessment of sleep in paediatric pain populations. We will then review established and emerging medical and psychological treatment strategies used to effectively treat these important difficulties. Practical suggestions will also be provided as a general and basic guide for treatment of children and teens with pain and sleep problems.

### Pain in children

For most children and adolescents, pain is a noxious experience that interrupts and negatively affects many aspects of function. As pain exists across a spectrum from acute and episodic to persistent and chronic, the disruptive effects of pain also range across a continuum from mild to disabling. Acute pain often plays an important protective role in alerting the sufferer to injury or illness and can therefore have a very disruptive effect on function, generally on a

relatively short-term basis. Recurrent or persistent pain can have a useful function but often results in prolonged and more significant impairment. Chronic pain can become highly disruptive of function but generally tends not to have a useful or adaptive function, sometimes resulting in a complex web of negative outcomes that can have widespread effects on a young person's life.

Clinically, when pain becomes disruptive of function, it is frequently reported by child and adolescent sufferers to result in a range of negative outcomes. These negative effects include impairment of physical function and activity levels, decreased school attendance and academic performance, cognitive interruption, mood problems, particularly anxiety and depression, decreased social activity including negative effects on friendships, and poorer quality of life (Dick and Pillai Riddell, 2010; Forgeron et al. 2011). The nature and severity of the effects of these problems can interact with each other and can be associated with several negative vicious cycles.

Amidst all of these difficulties, sleep is a primary factor reported to be negatively affected by pain. In clinical settings, sleep is commonly reported to be one of the major complications caused by pain and a primary source of difficulty associated with mood problems, school attendance and performance, cognitive function, and quality of life (Owens, 2005). It is not uncommon for one or more of the major negative clinical features associated with pain to improve markedly when treatment results in improved sleep.

### Sleep and pain

Sleep is of critical importance to the developing child. It has been found to be associated with physical health, growth, and function, development, learning, and cognitive function, several aspects of behaviour, mood, emotional regulation, and psychological health, coping, and family function (Durmer and Dinges, 2005; Forest and Godbout, 2000; Meltzer and Mindell, 2009 Mindell and Owens, 2003; Owens, 2005). Sleep problems are also associated with other health problems including cardiovascular disease, diabetes, obesity both in children and in adults (Cappuccio et al., 2008; Foley et al. 2004), and stress and other negative effects on parents of these children (Martin et al., 2007).

**Table 15.1** Sleep-related symptoms in the context of pain in children (but not pain specific)

<b>Daytime symptoms</b>	Irritability, hyperactivity, daytime sleepiness, fatigue, increased pain, behavioural problems, anxiety, lower frustration tolerance
<b>Bedtime symptoms</b>	Delayed sleep onset, irritability, bedtime battles, anxiety, hyperactivity, increased pain
<b>Sleep symptoms</b>	Wakefulness after sleep onset, lower sleep efficiency, fragmented sleep (microarousals), nightmares, worse parasomnias resulting from sleep fragmentation, night-time arousals, irritability, sudden awakenings, inconsolability.

While sleep problems in children and teens in the general population are common, it has been recognized that children and adolescents with pain may be at particular risk for sleep problems (Owens, 2011). For example, adolescents with inflammatory bowel disease reported poorer quality sleep with increased disease severity. The parents of those adolescents also reported that their children experienced more nightmares and other sleep difficulties and that disease severity was associated with higher levels of daytime fatigue and an increase in the amount of time that their children spent sleeping during the day (Pirinen et al. 2010). In another study, Lewandowski and colleagues (2010) found that pain ratings were predicted by longer sleep duration and longer sleep onset delay. Given that pain can have such a dramatic effect on sleep quality, duration, and fragmentation, understanding the interaction between pain and sleep and how to effectively co-assess and treat these difficulties can have broader positive implications on child health and well-being in a variety of ways. It is remarkable how many common negative outcomes are uniquely associated with pain and/or sleep. Each problem can have a dramatic impact on function, mood, and cognition (Palermo, 2009; Sadeh, 2007). When pain and sleep problems coexist, the nature and extent of problems arising from the association can appear to be more complex and dynamic rather than simply additive. Chronic pain may also affect the child's sleep patterns over time and result in behavioural manifestations such as daytime irritability, moodiness, hyperactivity, and sleepiness. Unresolved sleep issues may make pain more difficult to manage. Table 15.1 provides common examples of behavioural manifestations in children struggling with sleep problems and pain.

## Prevalence and impact of sleep problems

In recent years there has been tremendous advances in the study of the relationship between pain and sleep problems in children. Two prior reviews (Gagliese and Chambers, 2007; Lewin and Dahl, 1999) have highlighted the importance of sleep in the assessment and management of paediatric pain, and have summarized the prevalence of sleep problems among children with various painful conditions, such as headache, recurrent abdominal pain, sickle cell disease, musculoskeletal pain, and arthritis. There is a clear consensus that children with chronic pain are more likely to experience a variety of sleep difficulties than their healthy peers (Gagliese and Chambers, 2007). Estimates indicate that approximately 50% of children with chronic pain experience a significant sleep disturbance (Long et al., 2008; Palermo et al., 2007, 2011), in contrast to 10% to 20% in healthy peers. Sleep difficulties are also commonly experienced as a result of pain among children with intellectual and developmental disabilities (Breau and Camfield, 2011). Across studies and pain types, difficulties falling asleep (i.e. insomnia), night wakings, and daytime fatigue are the most common sleep disturbances in children with chronic pain (Gagliese and Chambers,

2007). Some conditions can be associated such as sleep disordered breathing has been reported to have a higher prevalence in children with sickle cell disease (Brooks et al., 1996; Fuggle et al., 1996). Not only are sleep problems more common in children with chronic pain, but the severity of sleep disturbances is generally related to pain intensity; children with more severe pain are likely to report a greater degree of sleep problems (Bloom et al., 2002; Miller et al., 2003).

Data evaluating the association between pain and sleep in children are emerging, most using self-report and subjective assessment tools. A small group of adolescent females with chronic musculoskeletal pain were found to have similar total sleep time compared to norms but significantly longer sleep onset latency, more night wakings, a later morning wake time, and more symptoms of daytime sleepiness using validated questionnaires (Meltzer et al., 2005). Some of these teens reported improvement in pain after a sleep period. Conversely, a study of children with polyarticular arthritis tracked pain severity and sleep quality over a period of 2 months and found that poorer sleep quality was associated with higher next-day ratings of pain (Butbul Aviel et al., 2011). These findings associating disturbed sleep and fatigue, with increased pain have been also found in other rheumatological conditions (Butbul Aviel et al., 2011) and result in lower quality of life (Gold et al., 2009; Long et al., 2008). There is currently adequate evidence to suggest that any programme involving treatment of pain should also address sleep parameters of the affected individuals.

A series of papers (Long et al., 2008; Tsai et al., 2008; Palermo and Owens, 2008; Valrie et al., 2008; Ward et al., 2008) published in a special issue of the *Journal of Pediatric Psychology* (2008, Volume 33, Issue 3) dedicated to sleep in children with medical conditions, have extended our current understanding of the importance of sleep in paediatric chronic pain. The results of these studies have confirmed that sleep problems are common in children with chronic pain, and highlight the importance of factors such as mood, stress, and daytime napping in helping to understand the relationship between pain and sleep in children with chronic pain. For example, Valrie and colleagues (2008) showed that, among children with sickle cell disease, a day with high pain was related to poor sleep quality that night, which was then related to higher pain the following day. The relationship between pain and sleep has been shown to be further exacerbated by high levels of stress (Valrie et al., 2007). Tsai and colleagues (2008) examined the important role of naps in children with chronic pain, finding that children with chronic pain were likely to engage in daytime naps to compensate for lost night time sleep, which may have a negative effect on night-time sleep.

Of concern, sleep problems in children and teens with chronic pain are associated with lower quality of life and a greater degree of functional disability (Chambers et al., 2008; Long et al., 2008; Palermo et al., 2007, 2008). Recent work examining behavioural and psychosocial factors associated with insomnia in adolescents with chronic pain has highlighted that, while sleep disruption may

initially be a result of pain, sleep difficulties may evolve into a primary sleep disorder.

## Relationships between sleep and pain

The interaction between pain, sleep, physical function, and emotional regulation is complex. Although the mechanisms of the interactions and pathogenesis of pain and sleep are poorly understood, it is probable that pain, sleep and emotion share common neurobiological pathways and neuronal mechanisms. The neurobiology of the specific pain condition based on its associated symptoms may have widespread effects that may be linked to sleep related cellular activity and neurotransmitter processing areas of the hypothalamus, amygdala, limbic region, and frontal cortical areas.

Recent studies involving neuroimaging and neurophysiology are shedding light on the altered functional and structural changes in chronic pain. For example, in fibromyalgia, the pain is thought to be neurogenic in origin and results from neurochemical imbalances that lead to amplification of pain perception and abnormal signal processing (Henry et al., 2011). This may be associated with changes in cellular activation or cortical sensory integration.

It has been suggested that other chronic pain syndromes also have similar dysfunction in pain processing within the brain, although the exact mechanisms have not been elucidated. Sleep deprivation or sleep fragmentation may further exacerbate the disruption in processing. It is then conceivable that the aberrant signal processing may not be related to pain alone, but potentially to other homeostatic mechanisms within the central nervous system, including the processes that govern sleep physiology and circadian rhythms. Whether poor sleep is the manifestation of underlying biological dysfunction or a result of such dysfunction remains to be determined. Of note, the same neurotransmitters that influence pain sensitivity such as dopamine, serotonin, and noradrenaline, are the same ones involved in sleep and emotional regulation (Saper et al., 2005).

## Assessment of sleep in children with chronic pain

The assessment and evaluation of children with chronic pain and sleep issues is both challenging and complex because of the potential bidirectional relationship and mitigating factors that affect both sleep and pain. The assessment of a child with chronic pain condition should include a thorough history of sleep practices, routines, cultural beliefs and values related to sleep, sleep preferences, and screening for possible associated sleep disorders (such as sleep disordered breathing, restless legs syndrome, periodic limb movements, or disorders of excessive sleepiness). The evaluation should also include a typical comprehensive medical history, including details about psychiatric, developmental, social history and medication use. Further specific inquiry such as previous medication trials or complementary alternative therapy trials should also be included.

There are validated tools developed for children with chronic pain (Kashikar-Zuck et al., 2010, 2011; Palermo 2009). Validated questionnaires such as the Children's Sleep Habits Questionnaire (Owens et al., 2000), or the Pediatric Sleep Questionnaire (Chervin et al., 2007) have been used to identify sleep problems in various clinical and research populations but are not specifically designed for use with children or teens with chronic pain. Subjective, self-report measures for documenting sleep are available such as various

forms of sleep diaries which require recall of information about sleep quantity and timing (<<http://www.sleepfoundation.org/http://www.sleepforkids.org/pdf/SleepDiary.pdf>>). An excellent detailed review of the strengths and limitations of subjective paediatric sleep measures is available (Lewandowski et al., 2011a).

Information on objective parameters of sleep and sleep quality in children with chronic pain are sparse and limited. An overnight polysomnogram, which involves monitoring multiple physiological signals related to sleep and breathing, is the gold standard of sleep assessment. Polysomnography has been widely used to document the presence or absence of sleep disordered breathing. The role of this test in populations with chronic pain is limited partially due to limited access to such testing in many geographic locations, a paucity of research related to its role in the care of these children, and the fact that, in many cases, monitoring only takes place over one night. Alternatively, actigraphy, a wrist-watch like device that uses accelerometers to monitor activity patterns, can provide ecologically valid objective information related to sleep. Actigraphs are extensively validated and widely used devices in sleep research with reasonable sensitivity and specificity. Moreover, in paediatric populations generally, actigraphs provide accurate estimates of total sleep time and sleep efficiency, but are generally poor at discerning wakefulness after sleep onset (Meltzer and Westin, 2011). Actigraphs have also been used in pain research in children to measure physical activity (Kashikar-Zuck et al., 2010; Long et al., 2008; Palermo et al., 2008).

As more ambulatory monitoring systems are developed, we can expect that such monitoring in the home environment will become more popular. What has been learned thus far is that polysomnography in children with juvenile fibromyalgia showed increased periodic limb movements in a subset of children but little is known about which children would benefit from having polysomnography testing (Tayag-Kier et al., 2000) without comorbid sleep complaints (Bromberg et al., 2011). Another study evaluating polysomnography in children with headache showed an association between migraine and sleep disordered breathing, and tension headache and bruxism (Vendrame et al., 2008) and less rapid eye movement sleep and slow wave sleep. Practically speaking, persistent sleep complaints or lack of improvement in symptoms with behavioural interventions would be reasonable indications for pursuing further detailed sleep evaluation, including polysomnography.

Another test to objectively measure sleepiness in children is the multiple sleep latency test. A patient is given nap opportunities at 2-hour intervals through the day, and the degree of sleepiness is documented objectively by determining how quickly the individual falls asleep using standardized testing parameters. However, the role of such testing in children with chronic pain is not known, especially in the context of medications that may be partially responsible for the daytime fatigue or sleepiness.

## Optimizing sleep in children with chronic pain

Treatment of children with chronic pain who also have comorbid sleep problems requires a multidisciplinary, and often a multimodal approach. The multidisciplinary clinics often include an anaesthesiologist specialized in pain management, nurses, physiotherapists, occupational therapists, and child psychologists with interest and expertise in pain but often not the sleep medicine specialist. Either

the addition of a sleep medicine specialist or involvement via consultation could help improve outcomes of both sleep and chronic pain. Despite the fact that pharmacological interventions are frequently used to treat insomnia in children and adults, the empirical evidence shows that psychological interventions are more effective in both children and adults, especially in the longer-term (Mindell et al., 2006a; Stiefel and Stagno, 2004).

There are emerging data about the use of behavioural and psychological treatments for children with chronic pain with positive results in improved pain intensity, functional impairment, and emotional functioning (Palermo, 2009). Cognitive-behavioural therapy (CBT) incorporates both cognitive strategies and behavioural techniques to improve sleep that have a well-established empiric basis in management of insomnia in adults. One randomized control trial provided CBT using Internet delivery of sleep-related advice during one session with promising results (Palermo et al., 2009). CBT does appear to be effective for functional disability in children with juvenile fibromyalgia but the role of sleep has not been specifically addressed (Kashikar-Zuck et al., 2010, 2012; Lewandowski et al., 2011b). Nevertheless, it is commonly accepted that sleep health counselling including healthy sleep habits (sleep hygiene) should be addressed as part of the treatment for chronic pain (Box 16.1). The added value of such interventions to an integrated pain programme warrants further evaluation (see Logan et al., Chapter 50, this volume).

## Psychological treatments

Treatment studies can be used to tease apart the bi-directional relationship between sleep and pain, as well as provide clinicians with needed empirical support for selecting and implementing appropriate interventions. Of particular interest to the current review are studies that have treated sleep disturbances in individuals with chronic pain using psychological strategies. These studies examine how sleep problems in individuals with chronic pain respond to treatment. They also highlight the impact of improving sleep on pain and associated symptoms such as mood. In order to better understand the relationship between sleep and pain, and to highlight what we know about evidence-based psychological treatment of sleep problems in children with chronic pain, we will first review the empirical evidence for psychological treatment of sleep problems in otherwise healthy children. Due to the small amount of research on children in this area, adult studies are included.

## Insomnia and sleep interventions

The most common sleep problem in both adults and children is insomnia. Approximately 30% of children and adults display some symptoms of insomnia and about 10% reach full diagnostic criteria for insomnia (Meltzer et al., 2010; Morin, 2010). This rate is even higher for individuals with chronic pain; up to 50% of children and 50% to 70% of adults with chronic pain report insomnia (Lewandowski et al., 2011b; Menefee et al., 2000). There are a number of treatment strategies that are effective in treating insomnia in adults. These strategies include sleep restriction (i.e. limiting total sleep time to number of hours currently sleeping and slowly increasing sleep time), stimulus control therapy (i.e. changing conditioned associations with bed and sleep, e.g., using the bed as a place for sleep only), relaxation exercises (such as progressive

muscle relaxation, guided imagery, deep breathing), and sleep hygiene (i.e. a range of strategies that lead to healthy sleep habits). These strategies, along with cognitive restructuring (i.e. identifying and challenging illogical and maladaptive thoughts related to sleep) have been combined into a multi-component treatment approach, labelled cognitive-behavioural therapy for insomnia (CBT-I). In adult populations, CBT-I has received strong research support, based on meta-analyses and systematic reviews, for the treatment of primary insomnia (i.e. insomnia without any other medical or psychological conditions; Morin 2010). Less is known about the use of this technique in children. Given that CBT requires cognitive skills that emerge as development progresses, using CBT-I methods would require matching the treatment task requirements to each child's individual needs.

## Sleep interventions for children

Research examining the effectiveness of psychological treatments for insomnia in children has focused on testing the various treatment components in isolation or in combination, but has not specifically evaluated CBT-I. The vast majority of research has been conducted with infants and preschoolers and very little intervention research has been conducted with school-aged children and adolescents. Also, there have been very few randomized controlled trials (RCTs) conducted to document the efficacy of sleep interventions for children of any age. Mindell et al. (2006b) conducted a review of treatment randomized trials in young children and found that in the vast majority, children demonstrated improved sleep with the use of behavioural interventions. Not only did the children's sleep improve (80% of whom demonstrated clinically significant improvement), but also improvements in children's daytime functioning and parent well-being were noted (Mindell, et al., 2006b).

The primary goal of sleep interventions in children is to create positive associations with sleep, establish bedtime routines, and learn relaxation or self-soothing skills. The interventions that are considered well established by research are: extinction (i.e. parent not responding to child's attempt to re-engage parent to provide external soothing), graduated extinction (i.e. parent ignoring their child's attempt to re-engage for predetermined length of time), and parent education (i.e. teaching parents about children's sleep and appropriate sleep hygiene). Strategies considered to be probably efficacious include: scheduled awakenings (i.e. pre-emptive waking schedule for which parents wake their child 15 to 30 min prior to the time of typical night awakenings) and bedtime fading (i.e. putting the child to bed at a time that he/she is likely to fall asleep quickly and once successful backing up bedtime in 15-min increments).

## Sleep interventions for children with chronic pain

Although there is strong support for some intervention techniques in certain age ranges, there is very little research testing the effectiveness of these interventions for children with physical or mental health diagnoses (Lewandowski et al., 2011b; Vriend and Corkum, 2011). There is even less research on children with chronic pain. Four studies have provided sleep intervention as part of a multicomponent treatment for pain (Bruni et al., 1999; Degotardi et al., 2006; Maynard et al., 2010; Palermo et al., 2009). Each of these studies is

**Table 15.2** Intervention studies which included a sleep component for treating children with chronic pain

Author	Participants	Design	Treatment	Outcome
<b>Child intervention studies</b>				
Degotardi et al., 2006	N = 67 (59 females, 8 males); fibromyalgia; mean age: 13.9 years (SD = 2.8, range = 8–20)	Pre-post design; outcome was measured by questionnaires on physical (e.g. pain, sleep quality, fatigue) and psychological (e.g. anxiety, internalization, quality of life) symptoms completed by parents and children	8 weekly sessions which focused on psycho-education about pain and sleep, sleep improvement, pain management, and activities of daily living. Sleep treatment strategies included sleep hygiene, relaxation, self-reward, stimulus control, sleep restriction, and cognitive restructuring. Treatment was based on a CBT treatment manual developed by the authors	Improvements reported across all measures, including decreased pain, somatic symptoms, anxiety and fatigue as well as improved sleep quality. 24% of the children were reported to be pain free at the end of the intervention. Both self-reports and clinical observations showed dramatic improvements. Results were based on participants who completed the intervention (34% attrition rate)
Maynard et al., 2010	N = 41 (30 females, 11 males); pain-associated disability syndrome; mean age: 13.8 years (SD = 2.8, range = 8–21)	Retrospective chart review; outcome was measured by information in chart on school attendance, medication usage, sleep, functional disability, coping skills, and mobility	Treatment through an interdisciplinary inpatient rehabilitation programme including several components. Psychological treatment focused on CBT for pain and anxiety and the use of shaping to improve functional ability. Sleep intervention included relaxation strategies at bedtime	Improvement in functional ability, physical mobility, as well as school status, sleep, and medication use
Palermo et al., 2009	N = 48 (35 females, 13 males); chronic headache, abdominal, or musculoskeletal pain; mean age: 14.8 years (SD = 2.0, range = 11–17)	RCT; Internet-treatment group (n = 26), waitlist control group (n = 22); outcomes (e.g. recording pain and activity levels) were measured by daily diaries and questionnaires pre- and post-treatment	Internet-delivered CBT intervention which included 8 weeks of modules focused on treating pain through relaxation training, cognitive strategies, parent operant techniques, communication strategies, and sleep and activity interventions. Sleep intervention included information on sleep and good sleep hygiene practices	Improvements in pain intensity and activity levels at end of treatment and 3-month follow-up. No improvement in parental protectiveness or child mood symptoms
Bruni et al., 1999	N = 70 (32 females, 38 males); migraine sufferers with poor sleep hygiene; mean age: 9.7 years (SD = 1.5, range = 5–15 years)	RCT, assigned to treatment (n = 35), no treatment (n = 35); outcomes were assessed by tracking duration, frequency and severity of migraines	Treatment included application of sleep hygiene guidelines, but these were not specified in the paper	Improvement in frequency and duration of migraines for treatment group, but no change in severity

described in detail in Table 15.2. Results across these studies were generally positive, with improvements in both pain and sleep, as well as other associated areas (e.g. functional disability, fatigue). A series of randomized trials conducted among adults with chronic pain conditions (Currie et al., 2000; Edinger et al., 2005; Jungquist et al., 2010; Rybarczyk et al., 2005) has yielded similar positive results. More intervention research in this area is needed, with a focus on demonstrating that improvements in sleep does indeed result in improved pain outcomes.

## Pharmacological treatments

Pharmacological therapy for chronic pain should take into consideration potential interactions with sleep. There are no approved medications for the treatment of insomnia in children or medications for chronic pain in children. Reviews about insomnia and treatment options in children are available (Owens and Moturi, 2009; Owens et al., 2005). Chronic pain in children is often managed with similar medications as in adults off label, but integration of behavioural strategies are often paramount, much like management

of childhood insomnia. Of note, many pain medications that are prescribed often have sleep-related effects. For example, tricyclic antidepressants and anticonvulsants often have sleepiness as a side effect which may help promote sleep. These same medications may also cause daytime sleepiness or fatigue which may further worsen functional adaptation in dealing with pain. In some instances, such as with the use of gabapentin for neuropathic pain, the medication may help reduce pain and possibly improve a comorbid sleep disorder such as restless legs syndrome. Selective serotonin reuptake inhibitors (e.g. paroxetine) may be used for treatment of comorbid psychological disorders rather than pain itself and the impact of these medications on sleep such as rapid eye movement suppression, or increased periodic limb movements (Vendrame et al., 2011) should not be overlooked. Similarly, opioid medications for chronic pain may worsen underlying sleep disordered breathing, or result in constipation and associated discomfort that impairs sleep. Controlled trials using medications for treating chronic pain in children and teens are lacking. Future research studies should add in components that address sleep specifically. (For more information on clinical use of opioids see Strassels, Chapter 45, and for

drugs for neuropathic pain, see Rastogi and Campbell, Chapter 48, this volume.)

## Key recommendations

Given the evidence to date, we recommend that children with pain and sleep problems be provided with a developmentally appropriate, evidence-based intervention for their sleep problems as one component of their pain management plan. A detailed description of these intervention strategies is beyond the scope of this review; however, Box 15.1 lists some healthy sleep habits for children and adolescents and Table 15.3 contains a list of resources. Some modifications or special considerations might be useful to consider when implementing sleep intervention for children with chronic pain (Smith et al., 2005). The clinician may have to explain to parents why treating sleep problems is important, as a study by Claar and Scharff (2007) found that parents did not see sleep interventions as likely to help with the treatment of pain in their children. It will also be important to develop sleep interventions that parents of children with chronic pain can readily access. For example, novel delivery methods, such as internet (Corkum and Davidson, 2011) or telehealth (Witmans et al., 2008) may help to reduce access barriers. Clinicians working with children with chronic pain may also want to consider the following when implementing sleep interventions:

- ◆ Managing pain will help the child be able to fall asleep and stay asleep. Also, making sure that medications taken by the child are not interfering with sleep.
- ◆ Many of the strategies used to help with pain management (e.g. proper diet and exercise) will also help with sleep. It is important that exercise does not occur close to bedtime and that foods that cause any intestinal distress not be eaten close to bedtime.
- ◆ Parents and children should be informed about the relationship between sleep and pain, so that they understand why it is important to treat sleep problems as part of the overall pain management plan. For example, it would be important to point out that poor sleep is associated with next-day pain as well as increased negative affect and decreased positive affect.
- ◆ Sleep hygiene is an important component for sleep treatment. For children with chronic pain, it is important that the bed/bedroom is not associated with any painful treatments (e.g. injections) and that the child's bed is as comfortable as possible in order to reduce any pain associated with sleeping.
- ◆ Given that children with pain may experience hyperarousal, it is important to include relaxation training as one of the sleep intervention strategies.
- ◆ Sleep restriction therapy should be used with caution given some evidence that sleep restriction can increase pain.
- ◆ Parents may require additional support when implementing sleep strategies. Many parents find implementing these strategies to be stressful and this may be more so for parents of children with chronic pain.

## Conclusion

There is much more to learn about which sleep treatment components are most effective in this population, as well as how we might

### Box 15.1 Healthy sleep habits for children and adolescents

- ◆ Ensure morning bright-light exposure
- ◆ Schedule daily physical activity (ideally earlier in the day)
- ◆ Avoid caffeine in the afternoon and evening
- ◆ Reduce (and avoid where possible) bright light in the evening and in the night
- ◆ Reduce stimulating activities before and at bedtime
- ◆ Set an age-appropriate bedtime
- ◆ Establish a regular, consistent bedtime routine
- ◆ Maintain a consistent schedule for weekdays and weekends
- ◆ Create an environment conducive to sleep: cool, dark, quiet, comfortable
- ◆ Remove electronics from the bedroom
- ◆ Use the bed only for sleep
- ◆ Monitor for side effects of medications that may affect sleep.

have to modify existing sleep interventions to enhance effectiveness in children with chronic pain. However, at the current time, it would seem reasonable for clinicians working with children with chronic pain to assess and treat sleep problems. At a minimum, treating sleep problems will reduce the number of issues with which the child and parent is trying to cope, and could potentially improve pain while enhancing overall quality of life.

There is now a strong empirical base to conclude that sleep disturbances are indeed a significant problem for children with chronic pain. There remains much important work to do in this area. For example, more research is needed to examine the developmental trajectory of the relationship between sleep and pain problems across childhood and adolescence, the impact of the kinds and quantities of medication used by children with chronic pain and how these relate to sleep (Chambers et al., 2008). Future research is critically needed to develop and test the impact of interventions addressing sleep and pain among children and adolescents with chronic pain.

### Case example: pain and sleep

Melissa is a 14-year-old girl with a 5-year history of recurrent abdominal pain, which had recently significantly worsened to the point that she was now unable to attend school. At the time of her pain clinic evaluation, Melissa was experiencing daily, severe stomach aches with no identifiable medical cause. When queried about sleep during her evaluation, Melissa noted that in addition to her pain she was experiencing significant difficulties falling asleep at night and would watch television in bed until late at night. Melissa was also having great difficulty getting out of bed at a reasonable time in the morning. Because she was not attending school, her parents tended to let Melissa sleep in to catch up on her sleep, and Melissa reported that she often napped in the afternoon while watching television and resting. Melissa reported feeling more irritable and fatigued during the day, and acknowledged that feeling this way was likely making it harder for her to deal with her pain. The pain management team recommended a comprehensive cognitive-behavioural intervention in order to help Melissa learn strategies to better cope with her pain as well as a graduated school re-entry plan. Melissa's sleep, in addition to her pain, was also identified as one of the primary treatment targets. The family was provided with basic information about sleep and sleep hygiene and links between pain and sleep problems. A session was scheduled to tailor those strategies to meet Melissa's needs and to help her parents coach and support her sleep changes. The importance of a regular sleep schedule, the removal of the television from the bedroom, and the negative impact of daytime naps on night sleep were discussed. As treatment progressed, Melissa noted significant improvements in her sleep and her ability to apply the pain coping strategies she was learning in clinic. At the end of treatment, Melissa was still experiencing mild stomach aches most days, but had returned to school, was sleeping much better, her mood had improved, and she reported feeling more energy and less irritability.

## CHAPTER 16

---

# Pain in children with intellectual or developmental disabilities

John L. Belew, Chantel C. Barney, Scott A. Schwantes, Dick Tibboel, Abraham J. Valkenburg, and Frank J. Symons

### Summary

In this chapter, it is argued that it is time to bring the burgeoning work on pain together and develop a coherent clinically-informed research agenda addressing the problem of pain among children with intellectual or developmental disabilities (I/DD). The chapter starts with an introductory section providing a short overview of the problem of pain among children with I/DD including many definitional and historical issues. Subsequent sections include a review of the epidemiology and impact of pain in children with I/DD, followed by a review of pain assessment and then pain management in children with I/DD. The chapter ends with a summary and conclusions relevant for future research and practice.

### Introduction

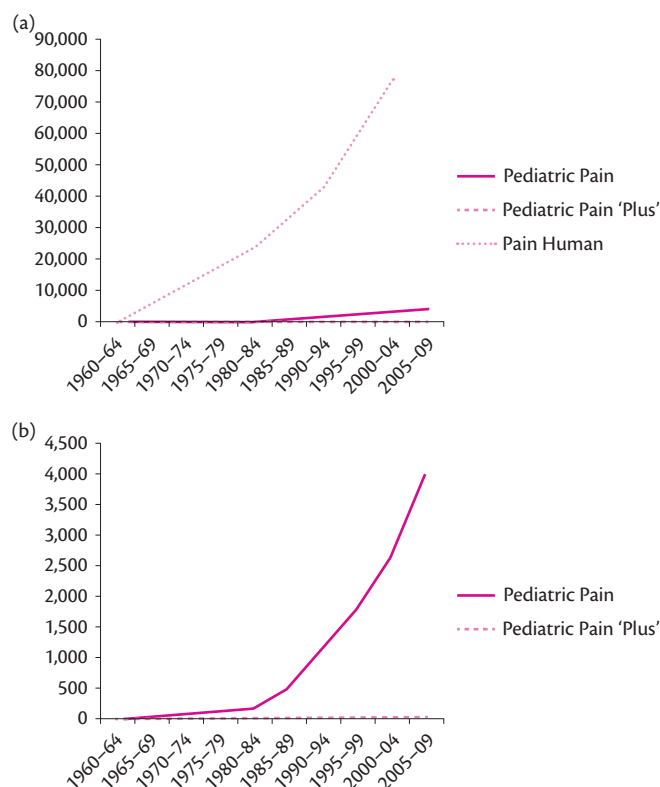

There is an enormous amount of scientific data about pain but comparatively little knowledge specific to children with intellectual or developmental disability. A PubMed search using the terms 'pain' and 'human' yielded over 100 000 publications for the 5-year period between 2005 and 2009 (the last full 5-year epoch) or, approximately 20 000 papers per year reporting on new discoveries, reviews, and theories regarding pain and the human condition. Only a fraction (3.7%) of those papers addressed paediatrics and pain (the topic of this volume). For that same 5-year period, there were a total of 30 scientific papers published specific to pain and children with I/DD—approximately 0.03% of the publication volume. Considering that approximately 1% to 7% of the world's population lives with an intellectual or related developmental disability (estimates vary widely between developed and developing countries; World Health Organization, 2001), the gap between what science has to tell us about pain in this population and what we probably need to know is striking (Figure 16.1). A contributing factor for this paucity of literature is most likely the routine exclusion of individuals with I/DD from research.

### Pain—important and prevalent in children with I/DD

There is little doubt that pain is a universal phenomenon causing tremendous human suffering and compromising the quality of life for countless individuals. The US congress declared 2001 to 2010 as the Decade of Pain Control and Research, however we estimate a decade devoted to pain research yielded fewer than 80 papers about pain in children with I/DD. And yet, there is no good reason to believe that pain is any less frequent in a child with a developmental disability or intellectual impairment, or that such an individual would be insensitive or indifferent to pain. Numerous functional limitations as well as the underlying neurological condition itself frequently confound the presentation of pain. Regardless of the degree of the disability, however, pain is often a part of daily life for children with I/DD (Oberlander and Symons, 2006).

The majority of scientific activity devoted to pain and children with I/DD in the previous decade has been to 'build a better mousetrap'—improving behavioural assessment techniques to identify accurately the presence of pain and its source or type, when reliable self-report is not an option. The fruits of this labour are manifest in several rating scales and questionnaires designed to measure pain intensity/severity and its expression (these are reviewed in detail in later sections).

Although the terms *intellectual disability* and *developmental disability* are familiar ones, we encourage the reader to pay careful attention to the explanation of these terms. The term I/DD includes a population of children that is highly heterogeneous: children with conditions of diverse type and aetiology (e.g. Down syndrome, cerebral palsy (CP), Rett syndrome) are included along with children with neurodevelopmental disabilities of unknown origin. Therefore our attempt here is to portray common features related to pain experience and management that are found across this diverse group, and specifically within certain subpopulations. By the very nature of their underlying condition children with I/DD are particularly at risk for painful experiences disproportionate to their typically developing peers. Common vulnerabilities children with I/DD face

**Figure 16.1** Cumulative frequency of paediatric pain research based on PubMed search results for full 5-year epochs using search terms 'pain', 'human', 'paediatric', and 'paediatric' plus 'intellectual disability', 'mental retardation', 'developmental disability' (a) and results for 'pain', 'paediatric', and 'paediatric plus' only (b).

with respect to pain include increased prevalence of painful conditions, both acute and chronic, higher rate of exposure to painful procedures (diagnostic and therapeutic), and neurosensory concerns that heighten the pain experience as well as complicate pain assessment and management.

Pain concerns are usually first addressed in a medical context. An initial obstacle health care providers (HCPs) often face when providing care for children with I/DD is the inconsistency and lack of detail typically found in medical records regarding a child's neurodevelopmental disabilities. While school records may contain the results of extensive neurodiagnostic testing, medical records often lack key information regarding the child's specific cognitive, communication, and adaptive behaviour abilities. This can make it extremely difficult for the HCP to establish the specific neurodevelopmental status of a child with I/DD (Salvador-Carrulla and Saxena, 2009). HCPs are left to guess or make assumptions based on 'clues' such as observed communication patterns and behaviour. Medical records frequently include non-specific use of terms like *autistic*, *mentally retarded*, or *developmentally delayed*. Used appropriately, the term *developmental delay* flags neurodevelopmental concerns in young children. However, this term is often included in the medical record of older children, even adults, when no more specific developmental descriptors have been established in the medical record.

### Defining intellectual disability

Intellectual disability (ID; previously referred to as 'mental retardation' and referred to as 'learning disability' in the UK) is defined by the American Association on Intellectual and Developmental Disabilities (AAIDD) as a 'disability characterized by significant limitations both

in intellectual functioning and in adaptive behaviour, which covers many everyday social and practical skills. This disability originates before the age of 18' (2012). Similarly, the International Association for the Scientific Study of Intellectual Disability (IASSID) considers ID as a 'significant intellectual deficit present from birth, or which originates at an early age or during the developmental period' (2012). There are key components to the definitions specific to the concept of 'intellectual functioning' and 'adaptive behaviour'. Intellectual functioning (i.e. intelligence) 'refers to general mental capacity, such as learning, reasoning, problem solving, and so on. One criterion to measure intellectual functioning is an IQ test. Generally, an IQ test score of around 70 or as high as 75 indicates a limitation in intellectual functioning' [i.e. greater than two standard deviations below average IQ] (AAIDD, <[http://www.aaidd.org/content\\_100.cfm](http://www.aaidd.org/content_100.cfm)>). A similar approach is used to determine adaptive function. Specifically, standardized tests are used to determine limitations in adaptive behaviour, comprised of three specific skill types including conceptual skills (e.g. number concepts), social skills (e.g. social problem solving), and practical skills (e.g. activities of daily living). On the basis of a set of standardized measures designed to specifically assess and evaluate intelligence and adaptive behaviour it is determined whether a child has an ID (see Salvador-Carrulla et al. 2011 for an interesting discussion of ID in the medical context.)

### Defining developmental disability

Developmental disability as defined in the US by the *Developmental Disabilities Assistance and Bill of Rights Act* (DD Act; PL. 98-527) refers to a 'severe, chronic disability' attributable to 'mental' and/or 'physical' impairments that are 'likely to continue indefinitely', resulting in substantial functional limitations in three or more 'major life activity areas: self-care, receptive or expressive language, learning, self-direction, capacity for independent living and economic self-sufficiency', are manifest by age 22 and require care, treatment or other services of lifelong extended duration. Some conditions may be included categorically, e.g. CP, spina bifida, autism. It is worth noting that unlike 'intellectual disability', classifying developmental disability does not benefit from a prescribed set of standardized assessment instruments, procedures, or professional training programmes. From a somewhat similar perspective, through the World Health Organization (WHO), The International Classification of Functioning, Disability and Health (referred to as ICF) also provides a classification system for health and health-related domains affected by disability. The domains are classified from body, individual and societal perspectives in two areas; (1) body functions and structure, and (2) activity and participation. The ICF is WHO's framework for measuring health and disability at both individual and population levels.

### Issues for I/DD created by the definition of pain

Pain, as defined by the International Association for the Study of Pain (IASP), refers to 'an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage' (Merskey and Bodguck, 1994). Because of problems created, in part, with the implicit requirement to self-report on the sensory or emotional experience, the definition was revised in 2002 with the clause 'the inability to communicate verbally does not negate the possibility that an individual is experiencing pain and is in need of appropriate pain-relieving treatment' (IASP, 2012). The overwhelming approach to considering pain, however, still relies extensively on self-report using language based on the spoken word (despite problems associated with almost exclusive reliance on

self-report as a 'gold standard'; see Schiavenato and Craig, 2010). The obvious problem created by the original definition for children with I/DD is that different combinations and functional levels of language/communicative, motor, and cognitive impairments associated with I/DD make self-report of a complex experience such as pain difficult if not impossible for some children. There is a likelihood that pain among many of these children cannot be measured in conventional ways (or perhaps even detected), resulting in painful conditions that are untreated or undertreated.

### Historical perspectives on pain and I/DD

Historically, there has been little recognizable sustained scientific investigation of pain among individuals with I/DD. At the same time, there is a long history of quasi-scientific perspectives regarding individuals with I/DD, including children, to be 'defective' in sensory function, particularly touch (including the ability to discriminate pain). So much so, as Sobsey (2006) points out, that the early tests for intellectual ability relied heavily on sensory discrimination tasks as well as notions of 'defects of vitality' and 'energy'. In his early account of autism, Bettelheim (1967) remarked that:

Why these children are so unresponsive to physical pain is difficult to know. It is the more baffling because they seem to pay so little attention to the external world and to direct all their attention to themselves. Thus, ... they should be more sensitive to what comes from inside them, including pain, than are normal people. But actually, the opposite is true. (pp. 58–59)

The historical lack of scientific attention given to the issue of pain in children with I/DD may be, in part, due to longstanding cultural 'norms' and personal beliefs, held by some and reflected in Bettelheim's thinking, that people with I/DD do not feel pain (insensitive) or do not care about pain (indifferent) (Couston, 1954; Sobsey, 2006). From this perspective, it follows logically that pain thresholds among individuals with I/DD would be expected to be elevated. Further, this view would suggest that individuals with I/DD who experience noxious stimuli would have reduced pain sensation compared to comparable peers (age, gender) without disabilities experiencing the same degree of noxious stimulation. The problem with this view—which has persisted to the present in different forms (Malviya et al., 2005)—is that studies are rarely designed explicitly assessing the dimensions considered to be deficient (e.g. pain thresholds). As a consequence, there is a scientific vacuum concerning the state of our knowledge about sensory function in relation to pain experience among individuals with I/DD (see Defrin (2004) for an example of a threshold study specific to I/DD).

Considering the core definition of pain, the revision notwithstanding, there is a danger that the 'elevated thresholds' viewpoint (either pain insensitive and/or pain indifferent) as the only position regarding pain may persist for children with I/DD. This may be particularly true for those children with multiple impairments (intellectual, motor, communicative) resulting in severe or profound disability—because of the great difficulty in reliable access to a subjective state (Breau et al., 2003a; Symons et al., 2008). Caregivers and healthcare professionals often report that pain signs are ambiguous, paradoxical, altered, blunted, or that they confuse pain signs with stress or arousal (Oberlander and Symons, 2006). Although there is great heterogeneity within the population of children with I/DD and some individuals may experience altered pain sensation (similar to the general population), there is no current compelling reason to think that all children with I/DD would have such wholly affected nociceptive physiological systems. (We are

aware of the fact that there are rare syndromes and conditions in which pain sensitivity is reduced or absent or that pain is sensed but the individual is indifferent to it (Nagasako et al., 2003).)

### Epidemiology

Most children with I/DD have associated disabilities and chronic health conditions; the likelihood of these conditions increases with the severity of the disability, as does the frequency of painful procedures for diagnostic or therapeutic indications. There are several reasons that children with I/DD are at higher risk for experiencing recurrent pain than their peers without disability, including painful conditions associated with the underlying cause of the disability; higher rates of painful medical procedures; physical therapy regimens that might be painful; impaired cognitive or communication abilities, resulting in under-recognition or delay in recognition that the individual is experiencing pain; and nociceptive pain experienced for extended periods of time increasing the risk of developing neuropathic pain or other chronic pain states.

There is very limited scientific evidence describing the incidence or prevalence of pain among the general population of children with I/DD. In daily pain diaries recorded by parents of non-verbal children with severe cognitive impairments over 2 weeks ( $n = 34$ ), 73% of the children had a painful experience on at least 1 day (Stallard et al., 2001). In a longitudinal study, children with moderate to profound ID ( $n = 94$ ) were found to experience pain for an average of 9 h per week (Breau et al., 2003b). Most of the painful events were non-accidental and were not associated with medical procedures but were related to gastrointestinal or musculoskeletal problems. The limited available evidence supports a reasonable assumption that individuals with more significant impairments of cognition and communication are more vulnerable to experiencing painful events that are not recognized or adequately managed. For example, although a parent might recognize that the child is experiencing pain, the child might not be capable of providing key descriptive information regarding the location, type, or timing of the pain. Recurrent, pervasive pain experienced by these children can result in extensive suffering and limitation. For example, ongoing pain issues have been associated with sleep problems of both the child and the family (Breau and Camfield, 2011; Hemmingsson et al., 2009).

The population of children with I/DD is extremely heterogeneous with regard to underlying conditions, degree of disability, functional limitations, etc. It is not surprising, then, that the literature addressing pain prevalence among children with I/DD in recent years includes papers on specific disabilities. For example, in the single study exploring pain among children with spina bifida ( $n = 68$ ), 49% reported experiencing pain weekly or more frequently (Clancy et al., 2005).

### Down syndrome

From 40% to 60% of children with Down syndrome have congenital cardiac or intestinal anomalies requiring surgical intervention, and are therefore exposed to pain associated with major invasive procedures (Valkenburg et al., 2010). Later in life, children with Down syndrome are at risk for orthopaedic problems associated with pain. Quantitative sensory testing studies in adults with Down syndrome have shown that the response time to sensory stimuli is prolonged, localization is more difficult, and that adults with Down syndrome are possibly more sensitive to heat pain (Defrin et al., 2004; Hennequin et al., 2000).

## Cerebral palsy

Recent population-based investigations place estimates of the prevalence of recurring pain among children with CP at between 50% and 75% (Doralp and Bartlett, 2010; Parkinson et al., 2010; Tüzün et al., 2010). The most common type of pain among children with CP is musculoskeletal pain. In addition, mobility limitations can result in secondary conditions that also cause significant pain, including pressure ulcers and constipation. The most common sites of pain include feet, legs, back, hips, hands, and arms (Engel et al., 2005). Children with CP often have low bone mineral density (attributable to limited weight-bearing, seizure medications, and other risk factors) which contributes to high fracture rates (Stevenson et al., 2006). It is important to note the heterogeneity of the population of children with CP, especially with regard to level of physical and cognitive limitations.

Although CP is often described in terms of motor impairments caused by anomalies in the brain, it is important to consider that the somatosensory system is also involved. The interplay between altered sensory functioning and pain experiences in individuals with CP has been increasingly recognized in a variety of conditions such as entrapment neuropathy (Frascarelli et al., 2005) or by applying sensory testing techniques (Riqueleme and Montoya, 2010) or related approaches to investigating sensory issues (Riqueleme et al., 2011). Although not all children with CP experience pain routinely, those who do are at risk for experiencing painful conditions through adulthood (Castle et al., 2007). With modern advances in medical management children with CP can be expected to live as long as their peers without disability (Strauss et al., 2007). The types of pain experienced in adulthood are likely to be associated with lifelong strain on muscles and joints (Turk, 2009).

## Assessment

Reliably and validly assessing a complex construct like pain is fraught with challenges. There is no equivalent of a 'pain thermometer' and the difficulty of the task, already made difficult in a paediatric setting, is amplified in the presence of a cognitive, communicative, or motor impairment associated with I/DD. As such, the verbal and cognitive functioning relied on for self-report of pain is compromised. Part of the challenge is also in the varied nature of I/DD. There are multiple levels of cognitive functioning, verbal abilities, physical and motor impairments such that no one assessment approach fits for all children with I/DD. Further, there are often multiple people involved in the care of children with I/DD (e.g. parents, teachers, physicians, nurses, physical therapists, etc.) and so pain assessment and management may often be regarded as someone else's responsibility.

## Self-report

Self-report is considered the 'gold standard' for pain assessment in other populations, however there is little evidence supporting its use with children with I/DD (Breau and Burkitt, 2009). For instance, Benini et al. (2004) taught children with I/DD on how to use self-report tools and then asked them to self-report on their own pain intensity and location following immunization. Despite having done well during training, only half of the children with I/DD were able to give consistent and accurate self-reports of their pain. Given the disparity between reporting pain during practice and during a real painful event, self-report is recommended to be

used with great caution and in conjunction with other types of pain indicators (Breau and Burkitt, 2009; Breau et al., 2007).

## Rating scales by proxy

To gain access to the pain condition when self-report has not proven reliable, observational methods have been used. Observational pain scales have been created based on measuring times when children are presumed to be in pain (e.g. during a needle stick, postoperative) versus times when children are not suspected to be in pain and examining behavioural cues that differ between the two conditions (Symons et al., 2008). A second approach has been to generate pain inventories or checklists based initially on interviews with caregivers that resulted in determining a list of pain cues. The initial lists are then reduced via item analysis and a rating scale is developed that in turn can be validated with different samples (Breau et al., 2002; Duivenvoorden et al., 2006; Hunt et al., 2004).

In multiple empirical studies there have been reports on the development of measurement tools that produce valid and reliable pain scores for children with I/DD (Breau et al., 2002; Hunt et al., 2004; Malviya et al., 2006). These measures focus on vocalizations, facial expression, physiological changes, and social changes. Each scale is unique (e.g. number of items, scoring method) but all share fundamentally similar pain descriptors. Three of the most promising paediatric pain measurement scales (NCCPC-R, PPP, r-FLACC) are reviewed in Table 16.1 (space precludes reviewing all relevant paediatric pain I/DD scales—see also Valkenburg et al. (2010) for a comprehensive scale review). It is important to acknowledge that it is sometimes difficult to distinguish pain from other responses such as fear, anxiety, sadness, or even contentment or excitement. Work continues with the emerging measurement tools to distinguish specific cues related to pain to provide a more clear understanding of when a child with I/DD may be experiencing pain. The scales have face validity, some empirical validity, and perhaps also clinical utility. All pain observation scales assess similar pain cues and all reviewed here have shown promising reliability and validity when used with children with I/DD (Breau et al., 2002; Hunt et al., 2004; Malviya et al., 2006). A different approach—used so far with adult samples with I/DD—developed by Bodfish et al. (2001; Phan et al., 2005) was to base the scoring of a scale on a standardized pain exam procedure. The most important choice particularly from a clinical perspective may not be *which* scale to use but rather to make a decision that pain *will be assessed* systematically and be aware that there are multiple measurement tools to choose from.

## Treatment

Adequate pain management in children with I/DD is accomplished when one finds a balance between caring for the individual and seeing the broad picture of analgesic management and pain mechanisms. As already described, these children are more at risk to experience acute and chronic pain. Comorbidities can cause pain and their treatment can influence pain management. Caregivers in all disciplines should select the most appropriate and adequate pain management for the individual. Pain expression could be less apparent than in other children, but that is not necessarily a good reason to delay analgesia. Unfortunately, with the paucity of evidence on pain management in this heterogeneous population, the broad picture in terms of evidence-based practice is not yet very clear. The starting point should be treatment according to

**Table 16.1** Sample paediatric pain assessment tools designed for intellectual and developmental disabilities

	<b>Paediatric Pain Profile (PPP)</b>	<b>Non-Communicating Children's Pain Checklist-Revised (NCCPC-R)</b>	<b>Faces Legs Activity Cry Consolability Scale—Revised (r-FLACC)</b>
Purpose	The purpose of the PPP is to provide an individualized measure for each child that is assessed. This scale is unique in that it asks caregivers to describe their child's good days and bad days	The purpose of the NCCPC-R is to provide one tool that is useful and accurate for all non-verbal children with IDD. The NCCPC-R quantifies pain responses observed by clinicians, parents, and caregivers regardless of how well they know the child. A postoperative version is available	The purpose of the r-FLACC is to provide a feasible method of quantifying an individual child's pain based on five domains and the specific criteria for scoring each of those domains. The original FLACC was revised to expand the descriptors for the subscales that were least reliable when used with children with IDD
Description of subscales and items	The PPP is a semi-individualized measure that allows caregivers to describe their child's behaviours related to pain. It also includes a 20-item questionnaires that is scored on a 0–3 scale	The NCCPC-R includes seven subscales (vocal, social, facial, activity, body and limbs, physiological, and eating/sleeping) each of which include multiple items that are scored from 0–3. There are a total of 30 items. The NCCPC postoperative version includes 27 of the same items but excludes the eating/sleeping subscale	The r-FLACC has five items (Face, Legs, Activity, Cry, Consolability) that are each scored from 0–2 based on the detailed descriptors specific to each item. The r-FLACC also provides caregivers the opportunity to write in other pain descriptors that may be unique to their child
Scale format	<i>Estimated time to complete:</i> 5–10 min <i>Scoring:</i> add item scores to determine a total score. The information written in by caregivers cannot be scored but provides valuable information specific to that child	<i>Estimated time to complete:</i> requires a 5–10-min observation period and <1 min to score. <i>Scoring:</i> item scores are added to determine the total score. A total score of 7 or greater indicates the child is in pain (accurate 77% of the time), and a score of 6 or less suggests the child does not have pain (accurate 84% of the time)	<i>Estimated time to complete:</i> 1–2 min <i>Scoring:</i> a total score of 0–3 is mild, 4–6 is moderate, and 7–10 is severe pain
Psychometric properties	<i>Sample used to test psychometric properties:</i> parents reported on 144 non-verbal children with various IDD (ages 1–18).  The PPP is a valid, reliable, and sensitive measure for individual children; however, it does not provide generalizable measures across children because the information written in is unique to each child	<i>Sample used to test psychometric properties:</i> Caregivers of 71 non-verbal children with various IDD (ages 3–17).  The NCCPC-R shows strong inter-rater reliability and internal consistency. This measure has also proved to have consistent scores over time. The NCCPC-R is sensitive and specific to pain and the scores are significantly related to parent pain rating	<i>Sample used to test psychometric properties:</i> 54 children ages 4–21 with various IDD pre and post surgery.  The r-FLACC showed inter-rater reliability and test–retest reliability. The measure showed strong correlation between observer FLACC scores and a parent's global pain rating
Recommendations	The PPP is useful for distinguishing a child's good days from bad days and it is recommended for monitoring pain over time. Because the PPP provides the opportunity for parents to add detailed information about the child's unique pain expression, this scale may be especially beneficial for parents to complete and leave with healthcare professionals during a child's hospital stay	The NCCPC-R is recommended for use in research studies because it is a standardized scale that is consistent across children. The NCCPC-R has shown strong psychometric properties across multiple populations and settings and is consistently accurate. There is a required observation time that allows for more accurate assessment because observation is a key part of proxy assessment	The r-FLACC demonstrates clinical utility as it is fast and easy to use. It can be individualized for each child which is beneficial for children with unique pain signs. Because it is individualized it is more difficult to compare across children and to have a consistent pain score that serves to determine when a child is in pain or not
Where to obtain the scale	< <a href="http://www.pppprofile.org.uk">http://www.pppprofile.org.uk</a> >	< <a href="http://www.aboutkidshealth.ca/En/Documents/AKH_Breau_Everyday.pdf">http://www.aboutkidshealth.ca/En/Documents/AKH_Breau_Everyday.pdf</a> >	< <a href="http://deepblue.lib.umich.edu/bitstream/2027.42/72254/1/j.1460-9592.2005.01773.x.pdf">http://deepblue.lib.umich.edu/bitstream/2027.42/72254/1/j.1460-9592.2005.01773.x.pdf</a> >

the WHO guidelines: by mouth, by the clock, and by the ladder (WHO, 1996, p. 36). For the perioperative setting, the American Society of Anesthesiologists published practice guidelines for acute pain management, with special recommendations for paediatric and cognitive impaired patients (2012).

Prospective randomized trials on analgesia in children with I/DD are scarce. Lower doses of intraoperative opioids have been observed (Koh et al. 2004; Long et al., 2009). Malviya et al. (2005) reported that 89% of the surveyed physicians had a tendency to prescribe subtherapeutic doses of analgesics in children with intellectual

disability. However, less than 10% of surveyed anaesthetists report giving lower doses of intraoperative opioids in children with I/DD (Valkenburg et al., 2012b). From these observational studies it is clear that it can be challenging to provide adequate analgesia in this heterogeneous population, there are concerns about the risk of side effects and toxicity, and so far there is no proper evidence for dosing analgesia in these children.

On the positive side, the development of the pain assessment tools for children with I/DD (reviewed earlier) and the establishment of pharmacological research in children will make it feasible to start with pharmacokinetic and pharmacodynamic studies specific to children with I/DD that, in turn, will provide evidence for decision aids to manage their pain (Valkenburg et al., 2012a). Walker advocates that pain management is more than the measurement of pain intensity; it should include a global assessment of inter-related current conditions and general health, nature of the surgery (if relevant), prior pain experience, current response to analgesia in terms of efficacy, and side effects (Walker, 2012).

### Pharmacokinetics

In general, children with I/DD are at greater risk to develop side effects (Reiss, 1997), but epidemiological data are missing. Case-control studies have shown that children and adults with Down syndrome are at increased risk to develop side effects and toxicity when treated with paracetamol (Griener et al., 1990) or methotrexate (Buitenkamp et al., 2010). After inhalational induction with sevoflurane, bradycardia and hypotension occurred in 57% of the children with Down syndrome versus in 12% of the children without Down syndrome (Kraemer et al., 2010). From observational clinical studies it is clear that there is variability in the dosing of analgesics and there is a high prevalence of comorbidities and treatment with psychotropic and anticonvulsant drugs in children with I/DD (Valkenburg et al., 2010).

For adequate pain management, it would be ideal to predict the pharmacokinetics (what the body does to a drug) and pharmacodynamics (what the drug does to the body) of the analgesics for the individual patient. It would mean that we have knowledge of the pharmacokinetic covariate effects (size, age, and organ function) as well as pharmacodynamic covariate effects (target organ perfusion, receptor sensitivity, efficacy, pharmacogenomic changes). As a group, children with I/DD are at risk for variability in both the pharmacokinetics and pharmacodynamics, due to, for example, the use of antiepileptic drugs, cerebral pathology, and genetic abnormalities such as trisomy 21. It will be a challenge to focus pharmacokinetic and pharmacodynamic studies on the drugs with the highest priority and the groups of children that are the most at risk for polypharmacy and side effects, but understanding of the factors that contribute to variability will help to individualize pain management.

### Antiepileptic drugs

Epilepsy is common among children with I/DD; incidence rates from 14% to 79% have been reported (Beavis et al., 2007). The more severe and extensive the cerebral pathology, the greater is the risk for epilepsy. Different antiepileptic drugs have varying degrees of protein binding and (liver) enzyme induction (Kofke, 2010). Chronic treatment with antiepileptic drugs can affect also the pharmacokinetics of other drugs that are metabolized by the same (P450) enzymatic pathway. This could be an explanation for

the finding that patients treated with antiepileptic drugs required higher doses of fentanyl during general anaesthesia (Tempelhof et al., 1990). A survey among Dutch anaesthesiologists revealed that around 75% adjust the dose of anaesthetic drugs in children treated with antiepileptic drugs (Valkenburg et al., 2012b). The interaction between antiepileptic drugs and analgesics as well as general anaesthetic drugs needs further attention.

### Pain treatment in cerebral palsy

A key component of pain management in individuals with CP is the reduction of muscle spasticity that contributes to musculoskeletal pain. A variety of therapeutic modalities are used to relieve pain associated with muscle spasticity (Aisen et al., 2011; Roscigno, 2002). Oral antispasticity medications include baclofen, dantrolene, diazepam, and tizanidine. Baclofen can also be delivered intrathecally by an implanted pump. Botulinum toxin A is used through multiple injections made to targeted muscle groups, after local anaesthesia with EMLA® and procedural sedation or under general anaesthesia (depending on location of injection, number of muscle groups to be treated, age, comorbidities and previous experiences). The toxin's inhibition of the release of acetylcholine at the neuromuscular synapse results in relief of spasticity that lasts 3 to 4 months—and for some individuals there is corresponding pain reduction. Through neurosurgery selective dorsal rhizotomy involves the cutting of sensory nerves to reduce muscle spasms (Grunt et al., 2011). A randomized controlled trial in 27 children with CP showed that epidural analgesia can give better analgesia and less muscle spasms after selective dorsal rhizotomy than intravenous morphine infusions (Malviya et al., 1999). Non-pharmacological interventions including massage and other interventions are widely reported as effective in relieving pain and promoting comfort (Glew et al., 2010), though there has been little research-based evidence demonstrating these benefits.

### Physical therapy

In addition to ID, many children with I/DD have a physical disability. CP causes motor disorders such as an altered muscle tone, impaired postural control, and muscle synergetic action (Martin et al., 2010). Motor development is often delayed in children with Down syndrome and they are at high risk for musculoskeletal disorders due to joint hypermobility and ligamentous laxity (Weijerman and de Winter, 2010). Physical therapy treatment goals are aimed at improving muscle strength, range of motion, gross motor function, endurance, and overall quality of life including pain reduction (Martin et al., 2010; Opheim et al., 2011). A survey among American physical therapists revealed that 80% of the respondents used pain assessment tools in children with I/DD. Distraction, procedural talk, and praise were the most used pain management techniques (Swiggum et al., 2010). Physical therapy will be used to treat and prevent pain from musculoskeletal disorders, but the therapy can be painful itself. Pain reduction should be evaluated over the course of physical therapy sessions and moderate to severe procedural pain should be treated.

### Conclusion

Moving forward, the clinical and scientific agenda is clear—to continue to leverage discoveries from basic and clinical pain research and apply them to solve the problem of pain for children with I/DD.

The remarkable achievements in pain scale development in the last decade for communicatively and cognitively compromised individuals needs to be converted to demonstrations that pain is being more effectively and efficiently identified and managed in health-care, rehabilitative, educational, and home environments.

Children with I/DD have been found to have a prevalence of chronic pain as high as 73%; this compares with recent estimates that approximately 33% of children in the general population experience chronic pain (Peterson et al., 2006; Roth-Isigkeit et al., 2004). Pain assessment is particularly challenging when encountering the array of individual cognitive and communication patterns found among children with I/DD. Early recognition and accurate assessment of pain is essential to prevent the development of pain syndromes resulting from untreated nociceptive pain. A broad array of instruments are available to support better pain management, and it is time for these instruments to be incorporated into randomized controlled trials and pharmacokinetic/pharmacodynamic studies in children with I/DD.

The notion of 'altered neural substrates' has only recently begun to be addressed (de Knecht and Scherder, 2011). At issue here is whether some point along the pain neuroaxis is compromised depending on the nature of the neural impairment leading to the intellectual or developmental disability. Although the specific brain pathophysiology underlying the myriad subgroups of I/DD is not often known, it may be reasonable to speculate on how known processing problems associated with some I/DDs and their neural correlates could affect pain (transduction, transmission, etc.). One reasonable framework could be to consider the three classic pain dimensions (sensory–discriminative, affective–motivational, cognitive–evaluative) as a way to organize imaging and neuropsychological assessment findings from different I/DD syndromes to consider whether specific features of pain processing are disrupted and whether the disruption co-varies with specific neurocognitive features of the I/DD. One pragmatic outcome of such an approach would be to broaden current approaches to pain assessment and management in the I/DD population beyond 'nociceptive' only pain (sensory–discriminative features) and push HCPs to consider relevant motivational, affective, and cognitive factors as well.

Clearly, there remains much work to be done. The weight of the (limited) evidence (provided, in part, by the scales developed during the last decade) suggests that children with I/DD have been subject to practices and procedures with little regard for their ability to experience or express pain. We need to continue to refine behavioural methods for the assessment of pain intensity, along with a measurement framework that can account for and predict the individual pain trajectory/course over time. More objective methods such as quantitative sensory testing (QST) might hold promise for the assessment of pain in children with I/DD, although modifications of these methods are needed to adapt to individuals not capable of cooperating with a standard QST protocol. In addition to cognitive and communication limitations, many other biopsychosocial factors are likely to contribute to inadequate pain management in this population, for example: atypical responses to treatment, polypharmacy, chronic pain conditions, repeated surgical intervention, genetic abnormalities, altered stress/arousal responses. Better specification of such variability will aid clinicians in developing pain management plans tailored to the needs of the individual child.

Research studies involving such a heterogeneous population must specify with as much detail as possible the specific features of study

subjects with I/DD. When possible, evaluations of levels of cognitive and communicative functioning would be preferable to blanket characterizations (e.g. verbal versus non-verbal). Better specification of I/DD related features would permit more accurate determination of how these variables interact with the main phenomena—some aspect of pain—under investigation. Trials should be developed and designed in accordance with recent consensus statements from the IMMPACT group further bringing in line results from studies with children with I/DD with other paediatric pain trials (McGrath et al., 2008). The Initiative on Methods, Measurement, and Pain Assessment in Clinical Trials (IMMPACT—a recurring internationally-recognized consensus group of pain experts from academia, government agencies, the pharmaceuticals industry, and self-help organizations) recommended a number of core pain outcome domains including: (1) pain intensity, (2) physical functioning, and (3) ratings of overall improvement. There is no reason that paediatric pain outcomes research focusing on children with I/DD cannot incorporate the same core outcome domains.

#### Case example: paediatric chronic pain I/DD case presentation

KL is a young girl (3 years, 6 months) with a past medical history significant for prenatal CMV (cytomegalovirus) exposure with resultant CP, spastic quadriplegia GMFCS (gross motor function classification system) class V, static encephalopathy, global developmental delay, intractable epilepsy, restrictive lung disease, disordered sleep, and cortical visual impairment who presents to clinic with a chief complaint of persistent distressing symptoms. The family has concerns that every 7 to 10 days, KL will have 2 to 3 days of increased crying, irritability, and discomfort. They state they have tried many medications including hydroxyzine, methadone, diazepam, oxycodone, ibuprofen, and acetaminophen. Of all the modalities the father states that ibuprofen and acetaminophen seem to be what gives the best relief; however, this is very transient. The day before some of these spells KL will usually be less engaged and they sense that she is 'winding up'. She will then have increasing amounts of 'whining' at which time they will administer ibuprofen or an extra dose of methadone. She will then enter an inconsolable crying spell where she will wake up and generally be crying all day and take a nap at 14.00. They can tell when KL is in pain as they have been using the TOPS scale and have been very adept at knowing when she is in distress. Additionally, the family states that when she is in one of these spells her heart rate is typically in the 170s and will stay there even when appearing calm. They state that there has been no major change in bowel or bladder function. They also do have concerns that she is hypertensive during these episodes. They feel as if some of these events can be precipitated by major temperature changes, which can cause her to 'lose it'. Additionally, they note an association with bowel or bladder discomfort that seems to 'set her off'.

#### Clinical decision-making

After reviewing the past medical history with the family, we worked with the notion that a significant amount of KL's distress was likely secondary to her underlying neurological insult with resultant

autonomic dysfunction, exacerbated by pain, discomfort, temperature swings, and bowel and bladder dysfunction. The initial intervention included treatment of the underlying autonomic dysfunction with optimized doses of gabapentin and cyproheptadine. Additionally, KL was weaned off of her scheduled methadone. Finally, we offered the following 'rescue plan' protocol when KL was experiencing an exacerbation of her distressing symptoms:

- a. Administer acetaminophen and ibuprofen in combination (180 mg and 120 mg respectively) via gastrostomy tube every 6 h as needed for pain or fever.
- b. If no effect in 30 min may administer diphenhydramine 12.5 mg via gastrostomy tube every 6 h as needed for agitation.
- c. If no effect in 30 min may administer diazepam 4 mg via gastrostomy tube every 6 h as needed for severe agitation.
- d. If no effect within 30 min, may administer propranolol 3 mg via gastrostomy tube every 6 h as needed for autonomic storming.

### Clinical outcomes

On 1-month follow-up, family had been able to enjoy positive changes in KL, including sleeping through the night. They stated that her irritability does continue, but it is intermittent, as opposed to constant, within the day. Most episodes during the day occur early in the evening, usually beginning at 18.00, and ending by 21.00. This was an improvement from the all-day 07.00 to 21.00 inconsolable crying. The family also notes that the 'rescue plan' has been working well at night-time; however, when tried during the day, it does not appear as effective. They state that overall they feel that KL appears more comfortable, she is more aware of her surroundings, and engaged at times when not irritable.

Based on this feedback, we further optimized her cyproheptadine and adjusted her protocol as follows:

- a. Administer acetaminophen and ibuprofen in combination (180 mg and 120 mg, respectively) via gastrostomy tube every 6 h as needed for pain or fever.
- b. If no effect in 30 min, may administer to give diazepam 4 mg via gastrostomy tube every 6 h as needed for severe agitation.
- c. If no effect in 20 to 30 min, may administer diphenhydramine 12.5 mg via gastrostomy tube every 6 h as needed for agitation.
- d. If no effect, may administer propranolol 3 mg via gastrostomy tube every 6 h as needed for autonomic storming.
- e. If no effect, may administer oxycodone 1.5 mg via gastrostomy tube every 6 h as needed for severe pain.

The 3-month follow-up revealed significantly improved symptoms and KL and her family were able to enjoy many symptom-free days with flare-ups treated by employing the 'rescue plan' protocol.

### Clinical issues

KL's distressing symptoms required both an extensive daily maintenance plan (cyproheptadine and gabapentin) as well as a 'rescue plan' protocol that could be administered by the family during flares. Educating and empowering the family while ensuring a plan that can be successful in the home was critical to the continued success in KL's comfort.

## CHAPTER 17

# Paediatric cancer pain

Jennifer Hickman, Jaya Varadarajan,  
and Steven J. Weisman

### Introduction

The publication of the World Health Organization (WHO)'s monograph *Cancer Pain Relief* in 1990 may be one of the groundbreaking events in the advancement of treatment for cancer pain (WHO, 1990). A result of this work was the first published guideline for the treatment of cancer pain in children (Berde et al., 1990; McGrath et al., 1990; Zeltzer et al., 1990). Since that time, several other guidelines and monographs have been published which provide very useful frameworks for the treatment of cancer pain (Anonymous, 1996; Benedetti et al., 2000; Miaskowski et al., 2004).

Although the incidence of childhood cancer has remained relatively stable over the last 35 years, the survival rate has increased dramatically. In 1975, approximately 14.7/100 000 children from 0 to 19 years were diagnosed with cancer (Howlader et al., 2012). Although the overall incidence did rise slightly to 17.0/100 000, mortality rate has decreased from 5.4/100 000 to 2.5/100 000 per year. In addition, the 5-year survival rates for paediatric cancer have improved from 61.7% to 83.1% between 1975 to 1977 and 2002 to 2008. Certain types of paediatric malignancy now have survival rates near or above 90% at 5 years (Hodgkin's lymphoma, 96.9%; Wilms' tumour 89.8%; and acute lymphoblastic leukaemia (ALL) 88.7%). These remarkable survival statistics have not come without a heavy burden and price. As described later in this chapter, these children have multiple challenges to overcome when exposed to aggressive treatments that include complex and repetitive surgeries, chemotherapeutic and radiation treatment regimens, and bone marrow transplantation.

As exemplified in the following case example, each patient seems to follow a unique trajectory and, for the pain clinician, will present unique challenges that require agility and flexibility to design satisfactory pain treatment protocols. Using a systematic approach that encompasses the notion that pain in paediatric cancer is usually the result of multiple intersecting causes will usually provide satisfactory results for the patients and their watchdog families supervising their care. For the continually decreasing numbers of children who cannot survive their disease, our palliative care colleagues can continue multimodal pain management in conjunction with their pain management resources to ensure a dignified and comfortable end of life.

### Case example

A 9-year-old boy with high-functioning autism was hospitalized for a several-week history of low grade fevers, progressive fatigue, pharyngitis, night sweats, and diffuse lymphadenopathy. Workup revealed an elevated white cell count and led to a diagnosis of high-risk acute myelocytic leukaemia.

He received three courses of induction chemotherapy and was in remission after the first course. Given his poor prognosis he was slated for an unrelated bone marrow transplant (BMT). His post-transplant course was complicated by pseudomonas bacteraemia, G-tube site infection, steroid-induced hypertension, sinusitis, mucositis, neutropenia, and high fevers suggestive of graft-versus-host disease (GVHD), eventually resulting in non-engraftment and rejection. He required multiple visits to the operating room for maxillary sinus taps and irrigations. He was treated with methylprednisolone, and then received a second haploidentical bone marrow transplant from his mother. He developed serum sickness with anti-thymocyte globulin and GVHD of the skin, needing immune suppression. His prolonged hospital course was further complicated by streptococcal viridans bacteraemia, viraemia, haemorrhagic cystitis, respiratory syncytial virus upper respiratory infection requiring ribavirin therapy, *Clostridium difficile* enterocolitis, feeding issues requiring enteral and total parenteral nutrition, episodic premature atrial contractions, intermittent prolonged QT syndrome, constipation, pancreatitis, hyperglycaemia, seizures, and chronic pain. Many of these issues were complications of therapy for his primary illness, but some were related to medications used for pain, insomnia, and mood. He was discharged after 7 months in the hospital.

Almost 2 years after his initial diagnosis, the patient's condition seemed to stabilize and his physical symptoms began to improve. He remained in remission, continued to be transfusion-dependent, but with no further evidence of GVHD. He was taken off systemic immunosuppression 3 years after BMT. He was able to wean a number of his medications and returned to school in a special education programme. As part of his recovery, he enrolled in a therapeutic riding programme and won the Child Equestrian Award 2 years ago. He is still considered high risk for secondary malignancies and is screened yearly.

## Aetiologies and characteristics of pain in cancer

Pain is one of the most prevalent symptoms in cancer (Collins et al., 2000; Ljungman et al., 1999; Miser et al., 1987a, 1987b). Pain in cancer can be a direct result of the disease, but it is largely due to cancer treatments or the combined long-term effects of both. The aetiologies of disease-related pain include bone pain from metastases or infiltration of tissues, somatic pain from solid tumours, visceral pain, and neuropathic pain (Box 17.1).

Treatment-related pain can be the result of chemotherapy, radiation therapy, acute and chronic postoperative pain, graft-versus-host disease, or procedure-related pain (Box 17.2).

## Pain from bone marrow infiltration, primary malignant bone tumours, and metastases

About a third of childhood cancers are leukaemias, the most common being ALL. Along with cancers of the central nervous system (CNS) they make up more than half of childhood cancers (Howlader et al., 2012). The rapid growth of leukemic blast cells from leukemic infiltration in the bone marrow results in diffuse bone pain. Pain from primary or metastatic bone disease is somatic in nature. It is often described as being 'aching'

### Box 17.1 Disease-related cancer pain

- ◆ Bone marrow infiltration (leukaemia, metastatic tumours)
- ◆ Visceral pain (invasion, obstruction, compression, bleeding)
- ◆ Somatic pain (rhabdomyosarcoma, osteosarcoma, Ewing's sarcoma, leukaemia)
- ◆ Neuropathic pain (neural compression/invasion, brain/spinal cord tumours).

### Box 17.2 Treatment-related cancer pain

- ◆ Medical procedures
- ◆ Acute postoperative
- ◆ Chronic postoperative: phantom limb, radiculopathies
- ◆ Chemotherapy:
  - ◆ Mucositis
  - ◆ Neuropathic
  - ◆ Extravasation burns
- ◆ Radiation therapy:
  - ◆ Mucositis
  - ◆ Skin burns
  - ◆ Local tissue injury
- ◆ Graft-versus-host disease
- ◆ Infection.

or 'gnawing' in nature in children who are able to communicate. The clinical presentation varies depending on the age of the child and the bones affected. Very young children, who are unable to communicate their pain, may present with a limp or an inability to walk. Children who have recently started walking may actually demonstrate regression in motor function. An older child, who is able to communicate, might report diffuse pain all over the body that is difficult to localize. Adolescents may localize the pain to a specific long bone and might mistakenly attribute it to a sports-related injury, thus delaying diagnosis and treatment. Cortical thinning could result in a pathological fracture with localized pain at the site. Treatment then would involve treatment of both the primary illness and its sequelae.

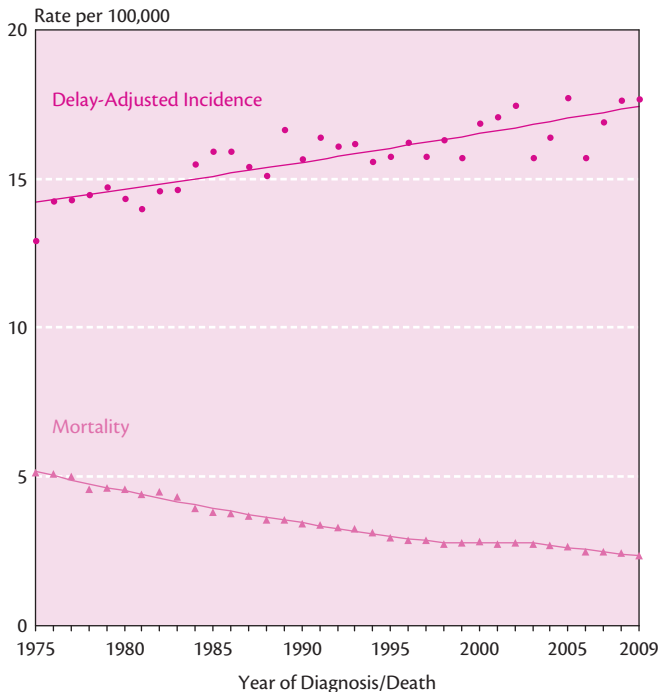

Malignant bone tumours such as osteosarcoma and Ewing's sarcoma can cause significant pain in the paediatric cancer patient. Direct tumour invasion causes bone pain from destruction of the normal trabecular bone pattern while periosteal new bone formation causes soft tissue inflammation and, in turn, pain. The bone pain from these processes is often severe and requires multimodal therapy. Solid tumours such as neuroblastoma can metastasize to both bone marrow and long bones. Its bone pain can be similar to that in the leukaemias.

Treatment of the primary cancer is the most effective method for managing cancer pain. In younger patients with leukaemia, decrease in the leukaemic burden following chemotherapy results in dramatic improvement of bone pain. Adolescents may be more challenging to treat due to more resistant disease, and require consistent analgesia. Local radiation therapy can also cause a reduction in bony pain. This will often be employed for palliation in situations where primary treatment has failed. Pharmacological treatment involves administration of opioids, often as continuous infusions or using patient- (PCA) or parent/nurse-controlled analgesia (PNCA). Adjuvant analgesics are also often employed. It is important to consider that in patients with bone marrow infiltration, there is often concomitant bone marrow suppression with thrombocytopenia. Use of non-steroidal anti-inflammatory drugs (NSAIDs) can therefore place these patients at risk for bleeding from both quantitative and qualitative platelet defects.

## Neuropathic pain

Neuropathic pain is the result of tumour compression or infiltration of peripheral nerves or the spinal cord. Direct injury to a nerve can also occur with soft tissue tumours in compartmental areas, such as with Ewing's sarcoma or rhabdomyosarcoma arising in the pelvis. Neuropathic pain can also occur as a result of inflammation of a nerve root from malignancy or infection. Reactivation of a herpes zoster infection can occur in the immune-compromised cancer patient causing neuropathic pain. Cancer treatment is a common cause of neuropathic pain. Vincristine is one of the chemotherapeutic agents known to cause neurotoxicity.

The pathognomonic feature of neuropathic pain is dysaesthesia, with or without a 'burning' quality to the pain. Patients may also complain of 'electrical' pain, paroxysmal, brief 'shooting' or 'stabbing' pain, or allodynia and hyperpathia. Neuropathic pain can be challenging to treat. Medications used include the adjuvant drugs such as tricyclic antidepressants, neuromodulators such as gabapentin, and local anaesthetics. Natural antidepressants such as St John's wort have also been used but with limited data on

**Figure 17.1** Cancer incidence and mortality in the United States 1975 to 2009. Reproduced from Howlader N et al. (eds), *SEER Cancer Statistics Review 1975–2009* (Vintage 2009 Populations), Section 28 Childhood Cancer by Site Incidence, Survival and Mortality, Figure 28.1, National Cancer Institute, Bethesda, MD, USA, available from <[http://seer.cancer.gov/csr/1975\\_2009\\_pops09/results\\_merged/sect\\_28\\_childhood\\_cancer.pdf](http://seer.cancer.gov/csr/1975_2009_pops09/results_merged/sect_28_childhood_cancer.pdf)>, based on November 2011 SEER data submission, posted to the SEER web site, April 2012.

effectiveness (Galeotti et al., 2010; Otto et al., 2007; Sindrup et al., 2001). Of the opioids, methadone is the one with the best data for being effective in neuropathic pain (Fisher et al., 2004; Lynch, 2005). Non-pharmacological approaches such as physical therapy, acupuncture, and cognitive-behavioural therapy (CBT) should always be considered.

## Visceral pain

Visceral pain results from infiltration and distension of thoracic and abdominal viscera with capsular wall stretching, organ compression by primary or metastatic tumour, hollow organ obstruction from tumour, tumour regrowth within an organ, or peritoneal cavity bleeding. It is poorly localized pain and described as 'deep', 'squeezing', and 'pressure-like'. When acute, it could be associated with nausea, vomiting, and diaphoresis. Primary tumours of the liver, such as hepatoblastoma or hepatocellular carcinoma, and tumours that metastasize to the liver, such as neuroblastoma, result in visceral pain.

In the case of visceral pain due to organ invasion or tumour regrowth, reduction in tumour size is the primary modality for treatment of pain. In the setting of intestinal obstruction from tumour growth, treatment is determined by the nature of the tumour. For example when obstruction is from Burkitt's lymphoma, treatment consists of chemotherapy and/or radiation, as surgery is not effective (Delarue et al., 2008; England et al., 2012; Gupta et al., 2007; Meyer et al., 2012). A multimodal approach that includes surgery, chemotherapy, and/or radiotherapy is common in solid organ abdominal cancers, such as Wilms' tumour. Postoperative pain from

surgical resection needs early implementation of opioids. Regional techniques are also helpful if not contraindicated by the presence of coagulopathy due to thrombocytopenia, disseminated intravascular coagulation, or the presence of acquired factor inhibitors. Epidurals are effective in management of postoperative pain and they can be tunnelled for longer-term use. Coeliac plexus blocks can be useful for unresponsive tumours such as bladder rhabdomyosarcoma, neuroblastoma or pancreatic tumours, but have not gained widespread acceptance in the paediatric realm despite reports of their efficacy in terminal cancer pain in adults (Berde et al., 1990; Tanelian and Cousins, 1989). Newer radiographic techniques such as three-dimensional rotational angiography may facilitate correct placement of coeliac plexus blocks in children (Goldschneider et al., 2007).

Regardless of the aetiology of visceral pain, it is necessary to implement treatment early to prevent the later development of central pain syndromes and visceral hyperalgesia, which can be extremely challenging to treat. CBT must be included as part of the treatment protocol.

## Pain with central nervous system tumours

CNS tumours are the most common solid tumours in childhood. The child often presents with symptoms suggestive of raised intracranial pressure from the mass effect of the tumour, such as headache or emesis. Surgical resection is undertaken for locally invasive tumours without metastatic potential such as astrocytomas (Sutton et al., 1995). Pain may persist from residual disease if complete surgical resection was not possible. In tumours that metastasize such as medulloblastoma, chemotherapy and/or radiation may be part of the treatment regimen either prior to or after surgical resection. Opioids are the mainstay of treatment in this population. Corticosteroids may be used to reduce cerebral oedema postoperatively. NSAIDs may be used if there is no contraindication due to the effects of chemotherapy or radiation therapy. The side effects of opioid treatment, such as nausea, emesis, and constipation, are best addressed pre-emptively, especially since the former symptoms can be confused with symptoms from the primary tumour. Adjuvant agents such as benzodiazepines may have a role in decreasing anxiety, facilitating sleep, and reducing muscle spasm postoperatively.

## Acute pain due to cancer treatment

As cancer treatment protocols evolve, treatment-related pain has become more prevalent. Common treatment-related type pain includes, but is not limited to, mucositis, infection, antineoplastic therapy-related pain, and postoperative pain.

Mucositis is the painful inflammation of the mucous membranes lining the digestive tract in response to cancer treatments with chemotherapeutic agents and radiation. It can affect the entire digestive tract from mouth to anus and can be quite painful. Symptoms include swollen gums, ulcerations in the mouth, diarrhoea, abdominal cramping, or rectal ulcerations. Pain due to these symptoms often precludes talking, eating, and, on occasion, swallowing. Treatment for oral lesions involves using various mouthwash mixtures which can have agents such as saline, sodium bicarbonate, hydrogen peroxide, sucralfate, nystatin, or viscous lidocaine. In more severe cases, PCA may be necessary (Dunbar et al., 1995; Mackie et al., 1991).

**Table 17.1** Adjuvant analgesics: major classes

Drug class	Examples
<b>Multipurpose analgesics</b>	
Antidepressants	
Tricyclic antidepressants	Amitriptyline (Elavil®) (tertiary amine) nortriptyline (Pamelor®), desipramine (Norpramin®); (secondary amines)
Selective serotonin reuptake inhibitors	Fluoxetine (Prozac®), paroxetine (Paxil®), sertraline (Zoloft®) citalopram (Celexa®), escitalopram (Lexapro®), fluvoxamine (Luvox®)
Noradrenaline/serotonin reuptake inhibitors	Venlafaxine (Effexor®), duloxetine (Cymbalta®), milnacipran (Savella®)
Others	Bupropion (Wellbutrin®)
Corticosteroids	Dexamethasone (Decadron®), prednisone (Deltasone®; Orasone®)
$\alpha$ 2-adrenergic agonists	Clonidine (Catapres®), tizanidine (Zanaflex®)
Neuroleptics	Olanzapine (Zyprexa®)
<b>For neuropathic pain</b>	
Anticonvulsants	Gabapentin (Neurontin®), topiramate (Topamax®), lamotrigine (Lamictal®), carbamazepine (Carbatrol®; Tegretol®), levetiracetam (Keppra®), oxcarbazepine (Trileptal®), pregabalin (Lyrica®), tiagabine (Gabitril®), zonisamide (Zonegran®), phenytoin (Dilantin®), valproic acid (Depakene®)
Local anaesthetics	Lidocaine (Xylocaine®; Lidoderm®), mexiletine (Mexitil®)
N-methyl-D-aspartate receptor antagonists	Ketamine, dextromethorphan, memantine (Namenda®), amantadine (Symmetrel®)
Other	baclofen (Lioresal®)
	cannabinoids
	psychostimulant drugs: methylphenidate (Concerta®; Metadate CD®; Methylin®; Ritalin®), modafinil (Provigil®)
Topical drugs	Lidocaine/prilocaine (EMLA®), Lidocaine 4% (LMX4®), capsaicin
<b>For bone pain</b>	
Corticosteroids	Dexamethasone, prednisone
Calcitonin	(Miacalcin®)
Bisphosphonates	Pamidronate (Aredia®), zoledronic acid (Zometa®), risedronate (Actonel®), Alendronate (Fosamax®)
Radiopharmaceuticals	Strontium 89, samarium 153
<b>For musculoskeletal pain</b>	
Muscle relaxants	Cyclobenzaprine (Flexeril®), orphenadrine (Norflex®), carisoprodol (Soma®), metaxalone (Skelaxin®), methocarbamol (Robaxin®), Tizanidine (Zanaflex®) Baclofen (Lioresal®)
Benzodiazepines	Diazepam (Valium®), lorazepam (Ativan®), clonazepam (Klonopin®)
<b>Adjuvants for pain from bowel obstruction</b>	
Octreotide (Sandostatin®)	
Anticholinergics	Hyoscine (scopolamine), glycopyrrolate (Robinul®), hyoscyamine (Levsin®)
Corticosteroids

Infection is common in children with cancer and can often be associated with pain. Common sites of pain include perioral, perirectal, abdominal, and skin infections. Severe abdominal pain can be due to typhlitis, infection of the cecum, in the immunocompromised, neutropenic patient (Hiruki et al., 1992). Treatment of the pain involves treatment of the infection. While being treated for the infection, analgesics such as opioids may need to be implemented on a short-term basis until the infection clears.

Injection of some chemotherapeutic agents may be associated with local pain at the time of injection. Thrombophlebitis

occasionally develops after injection of chemotherapy into a peripheral vein (Booth and Weiss, 1981). Intrathecal chemotherapy has been associated with arachnoiditis and meningeal irritation syndrome, which manifest as headache, nuchal rigidity, fever, nausea, and vomiting (D'Angio, 1983; Geiser et al., 1975).

Children with cancer undergo many surgical procedures such as port/line placements, tumour resections, peripheral and central biopsies, etc. These children have postoperative pain just as their non-cancerous counterparts do. Management of postoperative pain in the child with cancer is similar to the management of patients without malignancy. They will generally receive postoperative

**Box 17.3** Using adjuvant analgesics in the management of cancer pain

1. Consider optimizing the opioid regimen before introducing an adjuvant analgesic.
2. Consider the burdens and potential benefits in comparison with other techniques used for pain that is poorly responsive to an opioid, including: (a) opioid rotation, (b) more aggressive side effect management, (c) a trial of spinal drug administration, and (d) trials of varied non-pharmacological approaches for pain control (e.g. nerve blocks, rehabilitative therapies, and psychological treatments).
3. Select the most appropriate adjuvant analgesic based on a comprehensive assessment of the patient, including inference about the predominating type of pain and associated factors (comorbidities) or symptoms.
4. Prescribe an adjuvant analgesic based on knowledge of its pharmacological characteristics, actions, approved indications, unapproved indications accepted in medical practice, likely side effects, potential serious adverse effects, and interactions with other drugs.
5. The adjuvant analgesics with the best risk:benefit ratios should be administered as first-line treatment.
6. Avoid initiating several adjuvant analgesics concurrently.
7. In most cases, initiate treatment with low doses and titrate gradually according to analgesic response and adverse effects.
8. Reassess the efficacy and tolerability of the therapeutic regimen on a regular basis, and taper or discontinue medications that do not provide additional pain relief.
9. Consider combination therapy with multiple adjuvant analgesics in selected patients.

opioids, regional blocks, or neuraxial therapy to manage their pain. Patients who have been receiving preoperative opioids have usually developed some degree of opioid tolerance and should have their daily dose of opioids calculated into the postoperative treatment formula. This preoperative amount of opioid becomes their baseline to which additional opioids are added for the purpose of controlling new postoperative pain. If this principle is ignored, there will be dramatic under-dosing in the opioid-dependent oncology patient.

## Procedure-related pain

Pain and suffering from painful procedures that take place for diagnosis, treatment, and surveillance of children with cancer are overall the greatest sources of distress. Angela Miser was the first to report the burden of procedure pain in paediatric oncology patients in 1987 (Miser et al., 1987). Further delineation of problem took place in a series of reports from Sweden in 1999 and 2000. Ljungman reported that over 40% of pain during cancer

treatment was attributed by the patients and families to procedures (Ljungman et al., 1999, 2000). In a follow-up study of paediatric oncology patients undergoing procedures including bone marrow aspiration and lumbar puncture, persistently high pain scores were reported, in spite of ostensibly therapeutic doses of analgesia (Weisman et al., 1998). Aggressive and widely available interventions for procedure pain management are an essential component of paediatric cancer treatment. Interventions range from simple cognitive-behavioural distraction techniques to formal training in biofeedback or hypnosis to active use of topical anaesthetics to mild or moderate pharmacologic sedation and, finally, to using general anaesthesia, when needed.

Oncology patients experience venepuncture, intravenous line placement, port access procedures, intramuscular and subcutaneous therapies, plus more invasive lumbar punctures and bone marrow aspirations or biopsies. Preparation by the staff or even staff specialized in cognitive-behavioural techniques can help prepare these patients for the complicated road they will traverse (Zeltzer et al., 1989, 1990). Topical analgesics can greatly reduce the discomfort of the painful cutaneous procedures mentioned (see Stevens and Zempsky, Chapter 2; Taddio, Chapter 19, this volume).

Many children will receive chemotherapy via a lumbar puncture. The drugs themselves may result in headache, but as many as 20% of teens are at risk for developing postdural tap headaches when standard 20- or 22-gauge needles are used for sampling and drug delivery (Burt et al., 1998; Scher et al., 1992; Wee et al., 2008). Pain is first managed with conservative bed rest, fluids, and analgesics. If symptoms persist for several days, an epidural blood patch, performed by an anaesthesiologist or pain specialist will usually result in resolution of the headache (Safa-Tisseront et al., 2001).

Bone marrow aspiration and biopsy are common procedures for children with leukaemia, certain sarcomas, and neuroblastoma. Cutaneous management, as discussed earlier, is essential. In addition, deeper tissue infiltration that includes the periosteum is critical to effective pain relief. Distress during these procedures is well described, over 30 years ago (Jay et al., 1983; Katz et al., 1980). These are often done in conjunction with lumbar puncture and hence it is widely accepted that these children will not only have some form of cutaneous anaesthesia, but they will also have procedural sedation, moderate, deep, or even general anaesthesia (see Cravero, Chapter 20, this volume).

## Pain syndromes

Pain syndromes can occur as a consequence from the treatment of cancer. These syndromes can be a result of the surgical, chemotherapeutic, or radiation treatments undertaken while trying to cure the disease process. A variety of problems have been encountered in long-term survivors of childhood cancer that include, but are not limited to, chronic abdominal pain of uncertain aetiology, phantom limb pain, avascular necrosis of multiple joints, and neuropathic pain syndromes.

Amputation and limb-salvage procedures may be used as surgical approaches to achieve local control of a tumour that can lead to phantom limb pain. This pain is experienced when the patient continues to have pain appearing to come from where the affected amputated limb used to be. Krane and Heller (1995) found the prevalence of phantom pain in paediatric amputees to be 92%. The pain generally occurred within the first week after the loss of the limb.

The practitioner can use both pharmacological and non-pharmacological treatment modalities. The most important pharmacological treatment is effectively treating the pain preoperatively via the use of anaesthetic techniques such as an epidural. The use of epidurals prior to amputation can help prevent dorsal horn sensitization. After amputation, the focus becomes treating any neuropathic type symptoms. Chronic opioids are not usually effective in treating this type of neuropathic pain. A more successful approach usually involves the use of either gabapentin, pregabalin, or amitriptyline (or related tricyclic antidepressants). Non-pharmacological treatments or CAM treatments (complementary and alternative) can consist of hypnotherapy, massage, and acupuncture. An interesting approach to phantom limb treatment has emerged which uses mirror boxes (Chan et al., 2007; Ramachandran et al., 1996). This technique allows the amputee to place the remaining extremity into the mirror box. The projected image of the normal extremity appears to the patient to be the contralateral affected extremity. Repetitive therapeutic activity of the normal limb, viewed as the missing limb appears to 'retrain' and normalize neuronal pathways. Though phantom pain can be difficult to treat, in the paediatric population phantom pain tends to decrease over time regardless of the treatments.

Treatment regimens for cancer such as high-dose steroids and radiation treatments can have negative effects. These treatments can cause compromised blood supply to the bones which then leads to cell death in these areas resulting in avascular necrosis (AVN). The hip bone is the most common site, but knee, shoulder, and other bones can be affected. The incidence is 5% in childhood ALL and it usually develops during therapy although it has a latency period as long as 13 years after treatment is completed (Hanif et al., 2006; Mattano et al., 2000; Wei et al., 2000). Medical therapy for AVN is typically NSAIDs and physical therapy. However, if surgical intervention is needed it can include core decompression, bone grafting, osteotomies, or even joint replacement.

Chemotherapy-induced peripheral neuropathy (CIN) causes numerous debilitating symptoms and impairs functional capacity. Vincristine, vinblastine, cisplatin, oxaliplatin, and ifosfamide are most commonly implicated (Frisk et al., 2001; Gutiérrez-Gutiérrez et al., 2010; Le Deley et al., 2010; Lindeman et al., 1990; Reddy and Witek, 2003; Reinders-Messelink et al., 2000; Sandier et al., 1969). It can manifest with sensory symptoms, pain, motor symptoms, reflex loss, autonomic involvement, or a combination of these symptoms. Sensory symptoms tend to be most significantly manifested in the lower extremities. These manifest as itching, decreased or hyperactive responses to touch or vibration, and proprioception loss which can affect gait. Pain is an important side effect for many patients. It can occur early in treatment as painful paraesthesias or it can be a late and chronic consequence of treatment. Motor symptoms can be minor or more severe with athetoid movements and can progress to paralysis. There can be strength loss or symptomatic foot drop. Muscle cramping is also an underestimated motor manifestation. Reflexes can also be lost with the most common being the ankle reflex. Infrequently, patients develop symptoms of autonomic dysfunction. These can include orthostatic hypotension, constipation, or dysfunction of the urinary bladder (Windebank and Grisold, 2008). Prevention of CIN is the goal during treatment. There are agents that provide neuroprotection during therapy such as acetyl-L-carnitine, glutathione, vitamin E, or erythropoietin. These can be given to either prevent or even help treat developing

CIN. Supportive and symptomatic treatment is the mainstay of current CIN treatment. Management for CIN is similar to that of other neuropathic pain which entails analgesics, antidepressants, and antiepileptic drugs.

## Management of pain in cancer

Recommendations for pain management in this population should encompass not only what we consider to be traditional pharmacological interventions, but must be founded in a truly interdisciplinary model that should include behavioural and psychological interventions and appropriate physical modalities. Psychological distress is invariably secondary to the pain of the disease or treatment. Obviously, children with underlying psychological diagnoses will require ongoing management of this during the course of their diagnosis and treatment for cancer. It is important for the pain specialist to understand the extent of the child's disease and oncological treatment plan, the role of anticancer therapy, duration of treatment, expected duration of side effects from anticancer treatments, the child's prior pain experiences and the expectations for pain management amongst the patient, guardians and oncology/surgery care team members.

## Pharmacotherapy for management of cancer pain in children

The few analgesic studies that have been performed in children with cancer are limited by the paucity of subjects, and few are randomized controlled trials (Collins, 1998). Pharmacokinetic and pharmacodynamic properties of most opioids have been studied in children, but little information is available about oral bioavailability and potency ratios amongst the opioids (Collins and Weisman, 2003). There have been no controlled clinical trials of adjuvants drugs in paediatric cancer patients. The prescription of analgesics for children with cancer pain is based on various guidelines developed by content experts including the WHO guideline on cancer pain relief and palliative care in children (McGrath, 1996), the American Pain Society guideline for the management of cancer pain in adults and children (Miaskowski et al., 2004), the National Comprehensive Cancer Network practice guidelines for cancer pain (Benedetti et al., 2000), and *Supportive Care of Children with Cancer: Current Therapy and Guidelines from the Children's Oncology Group* (Altman and Children's Oncology Group, 2004). The original WHO ladder proposed that treatment of pain should begin with a non-opioid medication, progressing, as necessary, to a weak opioid and then to a more powerful opioid. It also included the possibility of adding adjuvants for neuropathic pain. Since its application into clinical practice in 1990 of the original guideline, the WHO stepladder has been quite useful for guiding the relief of pain from cancer (WHO, 1990). Its rationale and simplicity turned it into a very useful tool to unequivocally provide effective analgesia in malignant pain (American Pain Society, 2003). In recent years, several sources have proposed modifications to the original three-step ladder, recommending elimination of weaker opioids, use of stronger opioids as the first line in cancer pain treatment, using adjuvants early in the course of treatment, and incorporating neurolytic regional techniques in management when indicated (Jadad and Browman, 1995).

## Non-opioid analgesics

Non-opioid analgesics include acetaminophen, traditional NSAIDs, selective cyclo-oxygenase (COX)-2 inhibitors, and tramadol (a unique analgesic described later in this section).

Acetaminophen is one of the most commonly used non-opioid analgesics used in children. It has analgesic and antipyretic effects. It inhibits prostaglandin synthesis primarily in the CNS. It does not have the side effects of gastritis and inhibition of platelet function that are concerns with aspirin and most of the NSAIDs (Lesko and Mitchell, 1999). Although it has the potential for hepatic and renal injury, this is usually not a concern in commonly used therapeutic doses (Sandler et al., 1989). It does not have an association with Reyes syndrome (Halpin et al., 1982; Hurwitz et al., 1985). The antipyretic action of acetaminophen may be contraindicated in neutropenic patients in whom monitoring of fever is critical.

The NSAIDs include the traditional non-selective COX inhibitors as well as the selective COX-2 inhibitors such as celecoxib and partially selective meloxicam. They are useful analgesics in children with adequate platelet number and function, both alone, and in combination with opioids or acetaminophen. They have anti-inflammatory, analgesic, and antipyretic potential. Chronic use increases the concern for analgesic nephropathy, gastritis, and haemostatic effects. The selective COX-2 inhibitors have a lower risk of gastrointestinal and minimal haemostatic adverse effects, but the risk of renal compromise appears no different (Brater, 1999). There are no data on the safety, efficacy, and tolerability of COX-2 inhibitors in children with cancer. The non-selective NSAID choline magnesium trisalicylate reportedly does not interfere with platelet aggregation, but its use should be avoided in children with platelet counts less than 20 000 or with active bleeding (Collins and Berde, 1997; Stuart and Pisko, 1981).

Tramadol is a synthetic, centrally acting analgesic that exerts its effects through the  $\mu$  receptors, similar to opioids but not chemically related. It also stimulates the release of serotonin and inhibits reuptake of both serotonin and noradrenaline, thus simulating the properties of an antidepressant (Garrido et al., 2006). It is available in oral form alone in the US, but a parenteral form is being used in Europe and other countries. Long-acting forms are also available, allowing once-daily or twice-daily dosing. A concern with tramadol is that it lowers the seizure threshold, thus making its use challenging in cancer patients who could be on a multitude of other drugs with epileptogenic potential. It is currently a non-scheduled drug but concerns about its abuse potential have been raised (Grond et al., 1999).

## Opioid analgesics

Opioids are now considered the first line of treatment in cancer (see Strassels, Chapter 45, this volume).

### Morphine

Morphine is possibly the most widely used opioid for moderate to severe cancer pain in children. It can be administered by multiple routes including oral, sublingual, intravenous, subcutaneous, epidural, and intrathecal routes. An oral dose of 1 to 2 mg/kg/day is a reasonable starting point (Hunt et al., 1999). Oral morphine has a significant first-pass metabolism in the liver. A number of patients with cancer, however, require intravenous administration to address

the severe pain associated with their disease and its sequelae. An oral to parenteral ratio of 3:1 is usually used for administration (Cherny and Foley, 1996; Cherny et al., 1995).

Some patients benefit from the convenience of a patient-controlled analgesic (PCA) pump. Typical initial morphine doses for intravenous PCA administration range from 0.01 to 0.02 mg/kg for both a basal infusion and demand dose. Sustained-release oral preparations of morphine are available and are usually administered once or twice daily. Dosing at 8 h intervals can also be used in cancer patients (Hunt et al., 1999). Sustained-release preparations are appropriate *only* in children who can swallow pills, as crushing produces immediate release of a large dose of morphine. Sustained-release capsules with time-released pellets (e.g. Kadian®) may be an option in the child unable to swallow pills, as they can be mixed with semisolids (Broomhead et al., 1997).

### Hydromorphone

Hydromorphone is an alternative, when treatment is limited by the side effects of morphine. It is a safe drug to use in patients with impaired renal function, as its major metabolites are not active (Collins et al., 1996; Goodarzi, 1999). It is available for oral, intravenous, subcutaneous, epidural, and intrathecal administration and can also be used in a PCA pump, although dosing can be somewhat cumbersome in smaller patients. It has been reported to be an effective analgesic in several studies of patients with cancer (Babul et al., 1995; Broomhead et al., 1997; Dunbar et al., 1995, 1996; Weisman and Wishnie, 1996). It has been shown to be five to six times more potent than morphine in studies of children with cancer (Collins et al., 1996; Weisman and Wishnie, 1996). Little is known about its pharmacokinetics in infants and children (Babul et al., 1995; Murray and Hagen, 2005).

### Oxycodone

Oxycodone is a semisynthetic opioid used for moderate to severe pain. It is available as a slow-release preparation and as an immediate-release preparation with or without acetaminophen. Oxycodone has a higher clearance value and a shorter elimination half-life in children than adults and appears to have a potency of about 1.5:1 with morphine (El-Tahtawy et al., 2006; Kokki et al., 2004, 2006; Poyhia et al., 1993). There are no controlled trials studying the use of oxycodone in children with cancer, but it is widely used with presumed efficacy (Collins, 2001).

### Fentanyl

Fentanyl is a synthetic opioid approximately 50 to 100 times more potent than morphine with intravenous administration. It can be administered by intrathecal, epidural, transmucosal, and transdermal routes. It is an alternative for patients with dose-limiting side effects to morphine and hydromorphone (Cherny and Foley, 1996). It is commonly used in a transdermal form for patients requiring continuous opioids (Collins et al., 1999; Finkel et al., 2005). It has a proven track record for use in adult breakthrough cancer pain when administered by the transmucosal route (oral or nasal; Benitez-Rosario et al., 2005; Coluzzi et al., 2001; Payne et al., 2001; Zeppetella, 2000).

### Methadone

Methadone is a synthetic opioid with a long and variable half-life (12–24 h). The oral to parenteral potency ratio is 2:1. Methadone

provides equivalent but more prolonged analgesia than morphine (Berde et al., 1991; Davis and Walsh, 2001; Ripamonti et al., 1998). Its variable half-life predisposes to a risk of delayed sedation occurring several days after initiating treatment. Methadone does carry with it a cardiac risk with prolongation of QT intervals so serial electrocardiographic studies are advised in patients on long-term therapy (Kornick et al., 2003; Krantz et al., 2002, 2007). Methadone PCA has been reported as an effective delivery method in adults (Fitzgibbon and Ready, 1997; Shaiova et al., 2008).

In cancer patients, opioids should be administered at scheduled intervals to provide consistent pain relief. The dosing interval should be determined by the needs of the patient. Dose escalation may be required after treatment is initiated and periodically thereafter as tolerance to therapeutic effects is seen after a period of treatment (Portenoy, 1994b). Additional 'as needed' doses may be incorporated into the regimen for additional episodic breakthrough pain (Cleary, 1997). Oral and intravenous morphine and hydromorphone, and intranasal and oral transmucosal fentanyl are some of the options for breakthrough pain (Coluzzi et al., 2001; Zepetella 2000).

## Adjuvant analgesics

These are a heterogeneous group of medications that have a primary indication other than pain management, but are analgesic in some conditions (see also Rastogi and Campbell, Chapter 48, this volume). They are commonly prescribed in conjunction with primary analgesics (Portenoy, 1993). Their use is indicated when there is evidence of neuropathic pain, metastatic bone pain, anxiety, sleep disturbances, nausea and emesis, anorexia, poor appetite, cachexia, poor analgesic response to traditional analgesics, increased intracranial pressure, spinal cord compression, perineural oedema, and nerve compression (Lussier et al., 2004). They include drugs that come under the category of antidepressants, anticonvulsants, neuroleptics, psychostimulants, antihistamines, corticosteroids, and centrally acting skeletal muscle relaxants (George and Ahmedzai, 2000). Few adjuvants have been studied in the paediatric cancer population. To a large extent, drug selection, dosing, and monitoring approaches reflect extrapolation from the literature on non-malignant pain. Selection of an adjuvant is dictated by comorbid conditions and a comprehensive assessment of the patient. In some cases, the type of pain suggests the value of one category of adjuvant over another; in others, the existence of another symptom concurrent with pain favours the use of a specific drug.

## Tricyclic antidepressants

These are often considered first-line treatment in the management of neuropathic pain of various aetiologies. They have been used for a variety of pain conditions including cancer pain (Magni, 1991; Magni et al., 1987a, 1987b). Although commonly used in practice, there is limited evidence from controlled trials evaluating their efficacy in cancer patients.

Since the antidepressants have established benefit in diverse types of neuropathic pain, the strongest indication for their use as an adjuvant in the cancer population occurs in the patient with neuropathic pain who has not derived much benefit from opioids. Early use of antidepressants is justified when pain is accompanied

by depression. The sedating tricyclic antidepressants are often added when the patient complains of insomnia, while the anxiolytic selective serotonin reuptake inhibitors can be useful in anxious patients, and bupropion can be considered in sedated or fatigued patients.

## Corticosteroids

These agents may have a role in managing bone pain due to metastatic bone disease, neuropathic pain from infiltration or compression of neural structures, headache due to increased intracranial pressure, metastatic spinal cord compression, arthralgia, pain due to obstruction of a hollow viscus, or organ capsule distension.

Dexamethasone is the most frequently used steroid on account of its high potency, duration of action, and minimal mineralocorticoid effect. Prednisone and methylprednisolone can also be used. Corticosteroids produce analgesia by a variety of mechanisms, including anti-inflammatory effects, reduction of tumour oedema, and potentially by a reduction of spontaneous discharges in injured nerves. They can improve appetite, nausea, malaise, and overall quality of life (Watanabe and Bruera, 1994).

## Alpha 2 agonists

Clonidine, dexmedetomidine, and tizanidine may be used as adjuvants but side effects such as somnolence and hypotension can be limiting. Clonidine administered orally, transdermally, or intraspinally has been studied in non-malignant neuropathic pain. Intraspinal and epidural clonidine has been reported to be helpful in intractable cancer pain (Coombs et al., 1986; Eisenach et al., 1995). Limited experience with the use of dexmedetomidine as an adjuvant for refractory cancer pain has begun to appear in the literature (Roberts et al., 2011; Ugur et al., 2006). Hypotension occurs less commonly with tizanidine, which is an antispasmodic/muscle relaxant agent. There is evidence for its use in myofascial pain syndrome and headaches, but not cancer (Chou et al., 2004).

## Neuroleptic drugs

The neuroleptic drugs have been used for years in adults with cancer pain (Breitbart, 1998; Patt et al., 1994). There is little direct proof of their analgesic effect. These drugs do have profound sedating properties, which could explain the perception of co-analgesia (Richter and Burk, 1992). Methotrimeprazine appears to have analgesic properties in the setting of adult cancer pain (Beaver et al., 1966). However, this old neuroleptic drug is not being manufactured. Olanzapine (Zyprexa®) was reported to decrease pain intensity and opioid consumption, and improve cognitive function and anxiety, in cancer patients (Khojainova et al., 2002). Apart from these limited observations, evidence that commercially available neuroleptic drugs have analgesic properties is very meagre. The mechanism of analgesia and role as an adjuvant in paediatric cancer pain remains unclear. Given their potential for causing tardive dyskinesia and neuroleptic malignant syndrome, they are not routinely used as adjuvant analgesics unless delirium or agitation is present. The potential analgesic properties might allow a decrease in opioid consumption, which might in turn be helpful in resolving opioid-induced delirium. Neuroleptics tend to increase appetite, which may be desirable in some cancer patients.

## Adjuvants for neuropathic pain

### Anticonvulsants

Most view the anticonvulsants as the mainstays for managing neuropathic pain (Backonja 2000; Tremont-Lukats et al., 2000). Carbamazepine, phenytoin, and valproic acid have been the mainstay for years in treating neuropathic pain (Hardy et al., 2001; Harke et al., 2001; McCleane, 1999; Tanelian and Brose, 1991). Their use is limited by the potential haematological side effects, including neutropenia and thrombocytopenia. In recent years, gabapentin has been established in several types of non-malignant neuropathic pain, and it is now widely used to treat cancer-related neuropathic pain (Caraceni et al., 2004). Due to its proven analgesic effect in several types of neuropathic pain, its good tolerability, and low incidence of drug–drug interactions, gabapentin is now recommended as a first-line agent for the treatment of neuropathic pain of diverse aetiologies (Dworkin et al., 2007). The most common adverse effects are somnolence, dizziness, and unsteadiness. If titrated carefully, it is usually well tolerated.

Other newer anticonvulsants can be tried in patients who either have not responded satisfactorily to, have contraindications to, or have experienced adverse effects to gabapentin and other first-line adjuvants.

### Local anaesthetics

Intravenous infusion of lidocaine has been shown to be effective in non-malignant neuropathic pain (Attal et al., 2000). Randomized clinical trials of lidocaine in neuropathic cancer pain have not been promising, but anecdotal reports of benefit may justify its use (Bruera et al., 1992; Buchanan and MacIvor, 2010; Ellemann et al., 1989). Relief is usually transient. If lidocaine is found to be effective, but pain recurs, long-term systemic local anaesthetic therapy can be initiated with an oral drug, mexiletine. For the rare patient that responds only to intravenous infusions, long-term subcutaneous infusion may be an option (Brose and Cousins, 1991). The predictive value of a lidocaine infusion for subsequent effectiveness of oral mexiletine has not been established. It is therefore reasonable to start therapy with the oral drug in patients that have not responded to antidepressants or anticonvulsants. There is a high rate of adverse effects and discontinuation due to toxicity, especially gastrointestinal distress.

### N-methyl-D-aspartate (NMDA) receptor antagonists

These include the antitussive dextromethorphan, the dissociative anaesthetic ketamine, the antiviral amantadine, memantine, which is approved for Alzheimer's disease, and methadone. Ketamine has been shown to be effective in relieving cancer pain and reducing opioid requirements in children (Angelescu and Oakes, 2005; Bell et al., 2003; Finkel et al., 2007). It is typically administered by the intravenous or subcutaneous routes, but oral therapy has also been used (Kannan et al., 2002; Lauretti et al., 1999). Dextromethorphan has been shown to improve analgesia and decrease analgesic requirements in patients undergoing surgery for cancer, but long-term results are mixed (Mercadante et al., 1998; Weinbroum et al., 2003). Amantadine is a non-competitive NMDA antagonist with conflicting data on its efficacy in cancer pain (Pud et al., 1998). Memantine also supposedly possesses analgesic properties (Grande et al., 2008). The role of these agents in cancer-related neuropathic

pain is still unclear (Prommer, 2004). The d-isomer of the opioid methadone also blocks the NMDA receptor and might have a role in neuropathic cancer pain (Davis and Inturrisi 1999).

### Miscellaneous

Oral dronabinol and Marinol® have been shown to be effective in cancer pain but more studies are needed (Campbell, 2001; Huskey, 2006). There is limited and conflicting evidence for analgesic effects from benzodiazepines, but a trial of clonazepam can be justified in refractory neuropathic pain, especially in the presence of anxiety.

### Psychostimulants

There is evidence that psychostimulant drugs such as dextroamphetamine, methylphenidate, and caffeine have analgesic effects (Rozans et al., 2002). It appears, however, that their major use is in alleviating somnolence and sedation from opioids and other analgesics. The psychostimulants dextroamphetamine and methylphenidate have been used in children with cancer pain (Yee and Berde, 1994). Dextroamphetamine potentiates opioid analgesia and methylphenidate can reduce opioid-induced somnolence, improve cognition, treat depression, and alleviate fatigue. Potential side effects include anorexia, insomnia, and dysphoria. Modafinil, a newer psychostimulant, has been used to reduce opioid-induced somnolence in cancer patients (Webster et al., 2003). Although there are currently no scientific data supporting its use to reduce opioid-induced sedation, atomoxetine, a selective noradrenaline reuptake inhibitor, approved for the treatment of attention-deficit/hyperactivity disorder, has been used successfully in clinical practice.

### Topicals

Options include EMLA® (eutectic mixture of prilocaine and lidocaine), topical lidocaine, liposomal lidocaine, and lidocaine 5% patches (Devers and Galer, 2000; Rowbotham et al., 1996). Topical capsaicin causes depletion of substance P and selective blockade of the TRPV1 receptor from the nerve terminals and decreased pain perception (Ellison et al., 1997). It has been helpful in postsurgical neuropathic pain in cancer patients and in HIV-neuropathy (Simpson et al., 2008).

## Adjuvants for bone pain

An NSAID or steroid may be useful in multifocal bone pain. Calcitonin is useful in pain from bony metastases and neuropathic pain. It can be administered by the subcutaneous and intranasal routes for home care. There are also reports of epidural and intrathecal use in metastatic cancer (Blanchard et al., 1990). Monitoring of calcium and phosphorous is recommended. Bisphosphonates inhibit bone resorption. The analgesic efficacy of pamidronate and zoledronic acid has been well established in patients with metastases (Fulfaro et al., 1998; Rosen et al., 2001). These agents are also reported to decrease skeletal morbidity such as pathological fractures, need for radiation or surgery, spinal cord compression, and hypercalcaemia. Clodronate is an agent with good oral bio-availability (Ernst et al., 1992).

### Radionuclide therapy

For painful osseous metastases the use of radionuclide therapy has been reported in the adult literature. They may be effective as monotherapy or as an adjunct to conventional radiation therapy

(Anderson, 2002; Silberstein 1993, 1994; Silberstein and Williams, 1985; Silberstein et al., 1992, 1998). Radionuclides are absorbed at areas of high bone turnover. They include strontium-89, phosphorus-32, iodine-131, tin-117m, and samarium-153. There are reports of their use in older children and adolescents.  $I^{131}$  has been studied in children with painful metastatic bone disease from neuroblastoma (Cheung et al., 2001; Voute et al., 1988; Westlin et al., 1995). Given the potential for myelosuppression associated with their use, these drugs are considered when pain is refractory to other modalities.

## Adjuvants for musculoskeletal pain

Cancer patients often have pain that originates in muscle or connective tissue. Muscle relaxants include drugs in a variety of classes including antihistamines (orphenadrine), tricyclics (cyclobenzaprine), and others such as carisoprodol, metazolone, and methocarbamol. Although the efficacy of these drugs in muscle spasm is fairly well established, their efficacy for musculoskeletal pain in the cancer population is unclear. Their risk:benefit ratio relative to the NSAIDs or opioids is also unknown. Sedation, which is a side effect with these drugs, can become an issue if it compounds the sedation caused by opioids and other centrally acting drugs in these patients. Caution is also advised when using these drugs in patients with a history of substance abuse. If muscle spasm is believed to be the primary cause for pain, drugs with established effects on skeletal muscle such as diazepam, other benzodiazepines, the  $\alpha_2$ -agonist tizanidine, or baclofen should be used (Lussier et al., 2004). Botulinum toxin injections can be trialled for refractory musculoskeletal pain from spasms (Van Daele et al., 2002).

## Adjuvants for pain caused by bowel obstruction

Management of malignant bowel obstruction is challenging, especially when surgery is not an option. There is the need to control pain and other symptoms such as nausea, vomiting, and distension. Opioid escalation may not be an option due to dose-limiting gastrointestinal side effects or sedation. Anecdotal reports suggest that anticholinergic drugs, the somatostatin analogue octreotide, and corticosteroids may be useful in this setting. Anticholinergic drugs reduce gut motility and secretions. Octreotide has similar effects but possibly causes them more rapidly (Mercadante et al., 2000; Yuan et al., 2000). Methylnaltrexone has recently been approved for the treatment of opioid-induced constipation and appears quite efficacious in adults (Thomas et al., 2008; Yuan and Foss, 2000). Steroids may also have a role in malignant bowel obstruction but the mode of action is unclear.

## Complementary and alternative treatment options

There are multiple non-pharmacological therapies that can be employed for pain management in the paediatric cancer patient. These include the biobehavioural plus complementary and alternative medicine (CAM) therapies. CAM techniques are not often taught in medical schools, but can be powerful in the treatment of pain. These therapies are extensively discussed in Sections 7

and 8 and Chapters 59 (Weydert) and 60 (Zeltzer) in this volume. Specific issues related to malignancy are discussed in the rest of this section.

## Physical

Radiotherapy, chemotherapy, and surgery can result in acute and long-term injury to the heart, lungs, and skeletal muscles. These impairments can affect the child's physical fitness, necessitating rehabilitation during and after treatment. *Physical therapy* should be an integral part of the treatment process in order to minimize systemic effects and improve pain control. There is growing evidence for the positive effects of physical training on organ system function, fatigue and physical well-being in children during and after treatment for cancer (Huang and Ness, 2011; Marchese et al., 2003).

*Massage* is one of the most commonly reported CAM therapies among children with cancer. It has positive effects on pain, stress, anxiety, and the immune system (Hughes et al., 2008; Post-White et al., 2009). However, specific massage guidelines, including type and duration for the incorporation of massage for children with cancer have yet to be developed. Also, in a study of children with ALL, a daily massage over a one month period was found to have an impact on the immune system (Field et al., 2001).

Acupuncture helps with pain, but it can also help with common symptoms experienced by child cancer patients such as headache, nausea, and vomiting. Acupuncture has not been widely disseminated into pain treatment regimens for the paediatric population due to the belief practitioners have that children will be afraid of the needles. On the contrary, it has been shown that for those children who have been referred to acupuncture for various chronic pain syndromes, over two-thirds report that it was a positive experience and an effective modality for treatment of their pain (Friedman et al., 1997; Pitetti et al., 2001).

## Behavioural

There are many behavioural therapies that can be employed to assist with pain management.

Cognitive-behavioural therapy techniques are most commonly used to decrease distress and enhance a child's ability to cope with medical procedures (Chen et al., 1999; Liossi and Hatira, 2003; Zeltzer et al., 1991). These techniques have also been popularized as adjuvant therapy of the treatment of nausea and vomiting during chemotherapy treatments (Rheingans, 2007). During non-painful procedures such as radiotherapy, children can be assisted by using hypnotic techniques.

## CHAPTER 18

# Pain management in major paediatric trauma and burns

Greta M. Palmer and Franz E. Babl

### Summary

Pain management in major paediatric trauma and burns is challenging. It involves many phases including pre-hospital and emergency department care, ward management frequently including intensive care, and multiple operative and procedural interventions (as inpatients and later outpatients). Distress, anxiety, post-traumatic stress disorder (from the primary event and the ensuing in-hospital and post-discharge course), itch, neuropathic pain (in addition to pain of nociceptive origin), and sleep disorders frequently affect major trauma and burns victims and can persist long term. An evidence-based discussion follows of the pharmacological and non-pharmacological interventions employed during these various phases to address pain and the associated issues in these patients.

### Introduction

Paediatric patients with major trauma and burns represent significant pain management problems and present frequently to pre-hospital systems and emergency departments (EDs). Trauma and burn injury of moderate severity require ward and, when severe, intensive care unit (ICU) admission. Hospital stays may be prolonged. Surgery is commonly required, involving many surgical services. Pain, sedation, and anxiety management challenges occur throughout the patient's in-hospital stay and may persist during rehabilitation and post discharge.

### Aims

This chapter details pain management of children with major trauma covering their overall trauma care and the patient journey from pre-hospital, through in-patient care to discharge highlighting:

- ♦ Acute pain management pre-hospital, in the ED and perioperatively.
- ♦ Procedural sedation provided in the ward setting.
- ♦ Weaning and step-down analgesic regimens.

This chapter addresses considerations specific to burn injuries. Evidence for practices, when available, will be included. Where possible, variations in international practice are presented.

### Case example: trauma

A 14-year-old girl is inebriated and out with her teenage friends at midnight. They are 'train-surfing'—standing on top of a moving suburban train. Her two friends get off at a station but she decides to remain on and they see her balancing on top of the carriage, as the train moves away at speed. Shortly after leaving the station she is thrown from the roof of the train. Her friends see this and call emergency services with paramedics (ambulance officers) attending the scene within 10 min. She is crying in pain, confused, and smells of alcohol. She is tachypnoeic, tachycardic, and hypotensive. She has left chest wall tenderness and marked bruising over her upper abdomen; her right thigh is swollen, deformed, and tender.

### Case example: burns

A 2-year-old boy is reported to have pulled a large saucepan of hot water from a stove top. The scalding water has led to burns of his face and anterior chest. His mother puts him under running water in the shower for 2 min and calls emergency services. The paramedics find a screaming toddler with extensive blistering, swelling, and redness extending from his face to below his rib cage. He has no hoarseness or stridor. The rest of his body is not affected.

### Pre-hospital care

Care by paramedics occurs in a very different environment from hospital: resources are limited, backup is unavailable or only available remotely; initial assessment and care is often initiated in hostile environments, exposed to the elements with limited visibility; patients can be trapped requiring prolonged extrication; information can be limited and confusing; during transport assessment and procedures may be complicated by patient movement, crowding, and noise. Basic measures to assist with pain management include immobilisation and splinting of fractured limbs, the dressing of wounds, and covering of burns. Burns should be cooled under running tap water for 20 min, even if initial cooling is delayed (Allison and Porter, 2004; ANZBA, 2012) as supported

by porcine data (Rajan et al., 2009). While decreasing ongoing heat-related tissue damage and providing pain relief, cooling of burn wounds in children can cause hypothermia. With larger burns and younger children, the wound should be cooled and the patient warmed (Allison and Porter, 2004). Temporary burns dressings should be applied in the pre-hospital setting to reduce pain caused by contact and draft and maintain wound sterility while allowing inspection of the underlying burn. They should not be applied circumferentially as the burnt and periburn tissue can swell with oedema and blistering, causing further pain and vascular compromise. Such temporary burns dressings include cellophane type kitchen wrap and clean/sterile sheets (Allison and Porter, 2004; ANZBA, 2012).

There is limited high-level data on pre-hospital pain care for traumatic injuries in children. In adults and children with obvious traumatic injury, pre-hospital analgesic administration occurs in a low percentage of patients (Rogovik and Goldman, 2007; Swor et al., 2005). The level of pain care provided in pre-hospital systems is largely determined by the type of staff, their level of training and competency, and the protocols guiding pre-hospital analgesic use. Protocols permit the early administration of analgesics by paramedical staff without requiring permission from a remote medical control physician. Earlier increased use of morphine (Pointer and Harlan, 2005; Porter, 2004) occurred when pre-hospital protocols were modified to improve analgesic care.

*Morphine* and *fentanyl* are extensively used in the pre-hospital setting including in air-transported paediatric trauma patients (DeVellis et al., 1998; Krauss et al., 2011). There may be advantages of fentanyl over morphine (see Sethna et al., Chapter 46, this volume). In a systematic review of pre-hospital adult analgesia with intravenous (IV) morphine and IV fentanyl (Park et al., 2010), no patients required ventilatory support and only one patient in each group required naloxone. More recently intranasal fentanyl (INF) has been used in pre-hospital systems and in EDs. INF has similar analgesic efficacy and time to onset compared to IV morphine. A recent review (Hansen et al., 2012) summarizes paediatric INF use as investigated in a number of randomized controlled trials (RCTs). Comparison of INF with established analgesic agents showed similar decreases in pain scores. No major adverse events occurred with paediatric analgesic INF use and Glasgow coma scale (GCS) and vital signs were unaffected (Hansen et al., 2012). Minor adverse events include nausea, vomiting, pruritis, drowsiness, and a bad taste in the mouth. INF as a sole agent has a low incidence of emesis. The hazards to staff of IV or intramuscular (IM) administration in a moving vehicle combined with difficulties of establishing IV access in children makes INF attractive (Bendall et al., 2011; Johnston et al., 2011). INF is administered by either a mucosal atomizer device (MAD<sup>®</sup>; attached to a syringe for metered dosing) or a drop-by-drop technique. Usual dosing is 1.5 mcg/kg, divided between each nostril. This administration route bypasses gastrointestinal and hepatic elimination (Hansen et al., 2012; Panagiotou and Mystakidou, 2010). A maximum volume limit of 0.15 ml was suggested to avoid pharyngeal run off (Dale et al., 2002; Hansen et al., 2012). In past studies high concentrations of usually 100 mcg/ml to 300 mcg/ml have been used (Borland et al., 2007; Hansen et al., 2012). However, two recent paediatric studies have demonstrated similar analgesic efficacy of INF using the standard IV

solution (50 mcg/ml; Borland et al., 2011; Crellin et al., 2010). The standard concentration solution has advantages of wide availability, lower cost, and potentially less error because it avoids stocking two concentrations of fentanyl.

Limited data are available on pre-hospital use of other opioids such as diamorphine, nalbuphine, and tramadol (Hyland-McGuire and Guly, 1998; Mackenzie, 2000; Roberts et al., 2003; Vergnion et al., 2001; Ward et al., 1997; Woollard et al., 2004). Successful pre-hospital use of femoral nerve blocks has also been reported (Barker et al., 2008; Lopez et al., 2003; Park et al., 2010). Data in children for these agents and techniques are scant.

*Methoxyflurane* is an inhaled volatile fluorinated hydrocarbon anaesthetic agent available in a portable, compact delivery system. In Australia and some other countries, it is administered as an analgesic by paramedics from a plastic tube inhaler. The dose lasts approximately 30 min. The total weekly dose must not exceed 15 ml because of the risk of cumulative dose-related irreversible nephrotoxicity (Medical Developments International, n.d.).

Case series indicate that it is an efficacious analgesic in children and adults (Bendall et al., 2011; Grindlay and Babl, 2009). In addition to nephrotoxicity, it has been implicated rarely in hepatotoxicity (Joshi and Conn, 1974). The previous manufacturer, Abbot, withdrew it from the US market in 2001, and the US Food and Drug Administration (FDA) has since removed it from the drug register because of the safety concerns (FDA, 2005).

The mechanism of methoxyflurane's nephrotoxicity is unknown. Methoxyflurane is contraindicated in renal impairment, diabetes, concurrent use of enzyme-inducing drugs or tetracycline, a history of liver damage secondary to anaesthesia, malignant hyperthermia or hypersensitivity to fluorinated anaesthetics (Medical Developments International, n.d.).

*Nitrous oxide* (N<sub>2</sub>O) use on ambulances was described first in 1970 (Baskett, 1970). Recent reports indicate its continuing availability on ambulances in many pre-hospital systems (Bledsoe et al., 2005; Roberts et al., 2003; Siriwardena et al., 2010). It is usually administered in fixed concentration (50% N<sub>2</sub>O and 50% oxygen) with a demand valve that limits its utility to children over 4 years of age, who can generate adequate negative pressure to open the valve. It is also problematic in cold environments (Borland et al., 2002). Trauma patients who have potential air trapping (e.g. suspected pneumothorax) may not receive N<sub>2</sub>O.

*Ketamine* has also been used as an analgesic in the pre-hospital setting (Bredmose et al., 2009; Galinski et al., 2007; Jennings et al., 2012; Reid et al., 2011; Svenson and Abernathy, 2007). This includes use in paediatric trauma patients in parenteral and intranasal form (Bredmose et al., 2009; Reid et al., 2011; Svenson and Abernathy, 2007). In a physician-led air ambulance service, 164 children received IV or IM ketamine for analgesia for burns or for procedural sedation for fracture reduction (Bredmose et al., 2009). There were no adverse events or loss of airway, consistent with large scale ED data (Green et al., 2009a, 2009b). In an RCT of 135 adult trauma patients, IV morphine plus low-dose ketamine administered pre-hospital for moderate to severe pain provided superior analgesia to IV morphine alone but was associated with an increase in minor adverse events (Jennings et al., 2012).

Pre-hospital use of *non-pharmacological techniques* has also been described, including RCTs of acupressure in adults (Kober et al., 2002; Lang et al., 2007; McManus and Sallee, 2005).

## Emergency department care of trauma

### Definitions and classification of trauma

Trauma severity can be classified by injury extent, type, and severity. Injury extent centres around the number of body systems involved with multitrauma defined as involvement of two or more body areas. Injury type refers to penetrating versus blunt trauma. Injury severity groups trauma based on injury mechanism (such as a fall from a certain height) with findings during physical examination. High-risk trauma mechanisms have increased risk of clinical deterioration and require higher level care. A number of different paediatric trauma classification systems assist with patient triage, assess the severity of illness, and predict mortality (Marcin and Pollack, 2002).

### Overall trauma management

Pain management in children with major traumatic injuries should be embedded in a standardized approach to trauma care such as the globally used and taught system of the American College

of Surgeons' Advanced Trauma Life Support (ATLS®) Course (American College of Surgeons, 2008). ATLS® focuses on the recognition and management of life-threatening abnormalities of vital functions (primary survey and resuscitation) followed by a comprehensive systematic assessment of the trauma patient (secondary survey).

IV access is achieved to manage circulatory status, and is then available for IV analgesia. *Parenteral opioids* are the gold standard for analgesic management worldwide in the setting of moderate to severe trauma and burns management. If IV access is delayed in an unstable paediatric trauma patient, intraosseous access can be quickly established and permits fluid and drug administration including all analgesics (Von Hoff et al., 2008). If patients do not require IV access, such as in mild or isolated extremity trauma, INF provides an excellent alternative (Borland et al., 2007; Hansen et al., 2012) and its use can in itself reduce the need for IV access by 50% (Borland et al., 2008). Analgesic dosing is listed in Table 18.1.

**Table 18.1** Analgesic doses used in for pre-hospital or emergency department setting

Analgesic categories and agents	Formulation	Initial or loading dose	Subsequent dosing	Maximum dose	Notes
<b>Parenteral opioid</b>					
IV morphine	10 mg/1ml	50–100 mcg/kg	10–50 mcg/kg	No ceiling but if 200 mcg/kg used consider adjuvant therapy	Gold standard; histamine release may cause hypotension
IV meperidine	100 mg/ml	–	–		Due to abuse and neurotoxic metabolite rarely used now
IV oxycodone	10 mg/1 ml	100–200 mcg/kg	25–50 mcg/kg		IV formulation recently available
IV hydromorphone	2 mg/ml	10–20 mcg/kg	2–10 mcg/kg		
IV fentanyl	100 mcg/2 ml	1–2 mcg/kg	0.25–0.5 mcg/kg		Shorter onset and shorter acting; bradycardia can occur (with hypotension)
Intranasal fentanyl	100 mcg/2 ml Or 300 mcg/2 ml	1.5 mcg/kg (50% in each nostril)		3 mcg/kg	Onset within 10 min with duration of c.60 min
IV remifentanyl	1 mg, 2 mg ampoules	0.2–0.5 mcg/kg	Infusion 0.1–0.2 mcg/kg/min		Very potent; rapid onset and offset within 1–3 min; risk of respiratory depression/apnoea very high and so not used in pre-hospital setting
<b>5HT/NA/opioid effects</b>					
Tramadol IV Capsule/tablet Elixir	100 mg/2 ml 50 mg IR 10 mg/ml	1–3 mg/kg	1–2 mg/kg 6/24	100mg/dose 400mg/day	Lowers seizure threshold; avoid if serious head injury. Similar sedation, nausea and vomiting rates to opioids.  M1 metabolite active at mu opioid receptors.
<b>Non-opioid</b>					
Acetaminophen IV  oral tablet  Syrup	500 mg/50 ml or 1000 mg/100 ml  Typically 500 mg tablet  And various mg/ml concentrations available	15 mg/kg if IV Some use loading doses of 20–30 mg/kg orally	15 mg/kg 4–6/24	1 g/dose 60 mg/kg/day	Some institutions use loading doses; no load and 6/24 prescribing introduced for uniformity across authors' institution  Cost of IV 60–180x that of syrup-tablet dose

(Continued)

Table 18.1 (Continued)

Analgesic categories and agents	Formulation	Initial or loading dose	Subsequent dosing	Maximum dose	Notes
IV acetaminophen Neonates		10 mg/kg	10 mg/kg 6–12/24	Maximum depends on postmenstrual age	(Palmer et al., 2008)
<b>NSAIDs</b>					
Ibuprofen IV And oral Tablet, caplet Syrup	100 mg/1 ml 200 mg  100 and 200 mg/5 ml	5–10 mg/kg	10 mg/kg tds Give with meals if tolerating oral intake		Generally avoided in acute resuscitation phase as impair platelet adhesion (increasing bleeding risk) and glomerular filtration rate reversibly by 20% (Anderson, Chapter 43, this volume) and can precipitate renal failure in low output states
Diclofenac IV and rectal  Tablet	25–100 mg suppositories 12–100 mg	1–2 mg/kg	1–1.5 mg/kg 8–12/24	50–100 mg/dose	Suggested ceiling effect; higher doses prescribed in practice
Indomethacin IV PO				100mg/dose	
IV Ketorolac	60 mg/ml  10 mg/ml	US 1 mg/kg  Australia and New Zealand no load	0.5 mg/kg 6/24  0.2 mg/kg 6/24	Maximum 60 mg load then 30 mg per dose Maximum 10 mg/dose	Not licensed for use in children <12years Costly
<b>COX-2 inhibitors</b>					
Rofecoxib oral	50 mg tablet		1 mg/kg	50 mg/day	Was licensed for use in acute pain. Withdrawn by FDA post cardiac events
Celecoxib Capsule	100 mg and 200 mg Suspension (not marketed; Donnelly et al., 2009)	–	2–4 mg/kg 12/24	400 mg/day	Not licensed for use in acute pain; can disperse capsule contents in water
IV Parecoxib	40 mg powder		1 mg/kg daily	40 mg/day	
<b>NMDA antagonist</b>					
IV Ketamine	200 mg/2 ml	Analgesia: 0.5 mg/kg Anaesthesia: 1–2 mg/kg	0.1–0.4 mg/kg boluses or infusion per hour	If infusion used, usual dose 0.2 mg/kg/h with maximum 0.4 mg/kg/h	Used in children older than 2 years as adjunct or sole agent
<b>Benzodiazepines</b>					
Midazolam	5 mg/ml OR 5 mg/5 ml	0.05–0.1 mg/kg IV 0.5 mg/kg PO 0.4 mg/kg rectal/nasal			Amnestic and muscle relaxant to treat spasm or assist repositioning
Diazepam IV Tablet Syrup	10 mg/1 ml IV 1 mg/ml PO 5mg Suppositories	0.025–0.05 mg/kg IV 0.05–0.1 mg/kg PO/PR			To treat muscle spasm as an adjunct to opioids and regional, e.g. femoral nerve block
<b>Inhalational</b>					
Nitrous oxide	Entonox premix 50% adjustable system that delivers up to 70%	50–70% delivery for analgesia			Can cause nausea and vomiting; at higher concentrations can cause sedation. Avoid in closed pneumothorax, bowel obstruction
Methoxyflurane	Penthrox® whistle	0.1–0.3 MAC analgesic			

c = circa; FDA = Food and Drug Administration (US authority); IR = immediate release; IV = intravenous; NA = noradrenaline; NSAIDs = non-steroidal anti-inflammatory drugs; MAC = minimum alveolar concentration; NMDA = N-methyl D-aspartate; PO = oral; \* = registered trade mark; 5HT = serotonin

## Burns assessment and management

The majority of paediatric burns are hot liquid scalds. Contact and flame burns are less frequent but cause deeper injury. Inhalation airway and lung burns are particularly problematic and in fires can be associated with carbon monoxide poisoning.

The majority of paediatric burn patients can be managed in EDs alone (Rawlins et al., 2007). Criteria for admission and transfer to specialized burn centres have been published (ANZBA, 2004).

*Dressings* for superficial and partial thickness burns have been Cochrane reviewed (Wasiak et al., 2008). Twenty-six RCTs were assessed and most were methodologically poor. The use of biosynthetic dressings is associated with a decrease in time to healing and reduction in pain during dressing changes. The use of the traditional silver sulphadiazine as comparator in some studies was considered problematic as it was associated with delay in wound healing and increased number of dressing changes. The existing evidence is of limited usefulness in aiding clinicians in choosing an optimal dressing.

## Pain assessment

Pain assessment in the ED is often difficult, complicated by the urgency of critical medical issues with competing priorities, language barriers, patients affected by drugs or alcohol, and the difficulty of assessing patients with an immobilizing neck collar receiving oxygen or who are intubated, sedated, or medicated with muscle relaxants. In younger children, it is difficult to distinguish pain and distress. An inebriated, drug affected, or head-injured child or adolescent may be combative or uncooperative.

Pain is assessed using tools appropriate for the child's developmental stage, numeracy and literacy level, and intellectual capability (see chapters in Section 5 of this volume). Abnormal vital signs are sometimes used as proxies for pain, but in the trauma setting may reflect hypovolaemia and can be unreliable even in healthy subjects (Tousignant-Laflamme et al., 2005). The Critical Care Pain Observation Tool (CCPOT) has been developed to assess pain in critically ill ventilated adults. It has good inter-rater reliability (Gelinis and Johnston, 2007) with behavioural indicators providing more valid pain information than physiological indicators.

### Case example: trauma (continued)

After placing a neck collar and providing oxygen by mask, the 14-year-old train-surfer was assessed for pain. A patient-reported pain scale could not be obtained due to poor cooperation. A paramedic assigned her a numerical pain scale of value 10/10. While on the train tracks she was offered methoxyflurane and coached in using it, decreasing the paramedic assessed pain score to 4/10. She had an IV placed and received fluid resuscitation. Her right leg was splinted. During the transport to the trauma centre, she received IV morphine (5 mg) due to ongoing pain. She was estimated to weigh 50 kg. On ED arrival, she was assessed by the trauma team. On her secondary survey she was found to have a left clavicle fracture, multiple left rib fractures with pulmonary contusion, abdominal tenderness, and a right mid-shaft femur fracture. She was treated with oxygen by face mask and a second fluid bolus for hypotension. Her pain was assessed as 7/10. Her

right leg was very tender. She had a femoral nerve block placed by the emergency physician under ultrasound guidance. She ceased complaints of leg pain and was log rolled to assess her back. Due to ongoing clavicle, chest, and abdominal pain of 5/10, she was given two further boluses of IV fentanyl followed by IV ketamine (5 mg = 0.1 mg/kg) which settled her pain. However, she became less responsive with a GCS score of 10. It was unclear if the decrease in consciousness was due to her alcohol ingestion, the opioid and ketamine used, or a concomitant head injury. An urgent computed tomography (CT) scan of the head showed bilateral cerebral contusions without midline shift, an abdominal CT showed a small liver laceration. On return from the CT scan her GCS score was 8 and she was intubated for airway protection by rapid sequence induction using thiopental and succinylcholine.

### Case example: burns (continued)

The 2-year-old boy with scald burns was assessed to have 30-degree scald burns with large blisters developing over chest and upper abdomen. His burns were covered with a clean sheet by the paramedic services. He was screaming in pain. Paramedics administer INF at 1.5 mcg/kg. On arrival at the hospital, he had stopped crying. In the ED he was assessed to have no airway involvement and no circumferential burns were found. He had an IV placed and received hydration and IV morphine 0.1mg/kg. He was assessed by the burns team and his burns were covered with a silver containing dressing. Due to his burns' extent, he was admitted to a burns unit.

## Emergency department analgesia options

*Opioids*—if the patient is still in pain, but is ventilating adequately and does not have a depressed conscious state, further IV opioids may be titrated (see Table 18.1 for dosing): if pain is mild, at 20% to 50% of loading doses; if pain is severe, repeat loading is appropriate, depending on the timing of the last opioid dose pre-hospital. If two loading doses have been given within the expected duration of the opioid's effect and pain is still severe, then adjunctive agents can be administered while reassessing the child. Compartment syndrome must be considered in the setting of limb fractures and circumferential burns when opioid requirements escalate or pain is uncontrolled. Monitoring and early referral for pressure testing, compartment release, or escharotomy is essential.

*Tramadol* (see Rastogi and Campbell, Chapter 48, this volume) is an alternative to opioids, also available in parenteral and oral forms. It is not licensed for use under 12 years of age and has not been studied in paediatric trauma or burns patients.

*Non-opioid analgesics* are used to spare opioid use, reducing opioid-related side effects.

*Acetaminophen* (paracetamol) is an effective analgesic (Anderson, Chapter 43, this volume). As it is available in IV form, it is a useful intervention in the acute trauma and burns setting (Babl et al., 2011) as patients are fasting and plasma levels are rapidly achieved (over the rectal or oral route). Patients admitted with trauma or burns typically receive acetaminophen for several days to weeks. Their liver function should be monitored and the daily maximum prescribed should take expected duration and probably ideal body weight into account.

*Non-steroidal/non-selective anti-inflammatory drugs* (NSAIDs; Anderson, Chapter 43, this volume) are *not used* in the acute moderate to severe trauma and burns setting due to their platelet inhibiting and renal effects. Platelet inhibition (although reversible with all except aspirin) may exacerbate bleeding propensity, particularly if coagulopathy is present. NSAIDs reduce renal arteriolar flow and reversibly reduce glomerular filtration, via cyclo-oxygenase (COX)-2 inhibition. If the patient is volume deplete, from blood or extracellular fluid loss (due to trauma and burns respectively), this NSAID effect may precipitate renal failure (Musu et al., 2011).

The *N-methyl-D-aspartate (NMDA) antagonist* ketamine (Cravero, Chapter 20, this volume) is used in the major trauma/burns ED setting usually as a second- or third-line agent to IV opioids and IV acetaminophen when pain is still problematic. It is generally given as intermittent boluses of analgesic doses of 0.1 to 0.2 mg/kg every 10 min (i.e. 10% of an anaesthetic dose). Morphine sparing efficacy of 0.2 mg/kg IV over placebo was found in adult trauma patients ( $n = 65$ ; Galinski et al., 2007). Ketamine is not a respiratory depressant in its own right; however, it should be carefully titrated using a maximum single bolus of 0.5 mg/kg as opioid-induced respiratory depression can be precipitated once analgesia is achieved.

*Benzodiazepines* (BDZs), such as midazolam, diazepam, lorazepam, may be used in these patients' acute management for their muscle relaxant, anxiolytic, and sedative properties. They are used to supplement parenteral opioids or a regional block (e.g. fractured femur) to alleviate muscle spasm. They are used if the patient has escalating anxiety and/or distress (Kennedy, Chapter 34, this volume) not responding to analgesia and opioid titration. Midazolam has the additional benefit of antegrade amnesia and rapid onset (see Table 18.1).

Single-shot *nerve blocks* in trauma in the ED are useful (Barnett, 2009). Their application in trained hands is easily achieved, reducing or avoiding the need in multitrauma patients for opioids. In major trauma, a frequently used and useful block is the *femoral nerve block*. Paediatric femur fractures generally occur in the mid-shaft which is supplied by the femoral nerve (Barnett, 2009). Bupivacaine is usually used because of its longer duration of action. Following paediatric anaesthesiologists' practice (Flack and Anderson, 2012; Tsui and Suresh, 2010), the availability of ultrasound machines in EDs allows confirmation of the target nerve's position and avoids unwanted puncture and intravascular or intraneural injection (Frenkel et al., 2012; Reid et al., 2009). The alternative to a femoral nerve block is the fascia iliaca compartment block which has been successfully used in children in the ED. This block (performed without ultrasound; using ropivacaine) was compared to IV morphine for paediatric femoral fractures. It provided clinically superior pain management from 0.5 to 6 h (Wathen et al., 2007).

$N_2O$  can be used where short-acting sedation and analgesia is required for procedures associated with pain, discomfort or anxiety (see Cravero, Chapter 20, this volume). It can be used for minor trauma, instrumentation, and vascular access (Krauss and Green, 2006; Mace et al., 2008).  $N_2O$  should be combined with analgesia and topical, local, regional, or IV regional anaesthesia whenever possible to enhance the relatively weak analgesic properties of the agent for trauma-related procedures (Babl et al., 2008a). To achieve analgesia for painful procedures,  $N_2O$  can be combined with other techniques, such as INF (Seith et al., 2012), oral analgesia, and a haematoma block (Luhmann et al., 2006) or IV regional anaesthesia (Bier's block).  $N_2O$  reduces recall (Babl et al.,

2008a; Kanagasundaram et al., 2001).  $N_2O$  up to 70% for procedural sedation and analgesia is usually well tolerated by children with a low incidence of minor adverse events (5–8%: including vomiting, nausea, dizziness, and light-headedness) and rare serious or potentially serious adverse events (Babl et al., 2008b; Zier and Liu, 2011). Apnoea, aspiration, or the need for airway intervention has not been reported in large series after single-agent use of  $N_2O$ . In trauma patients  $N_2O$  should be avoided in patients with chest trauma and the possibility of an expanding pneumothorax or in head injured patients where there is a possibility of expanding intracranial air.

$N_2O$  may also have adverse effects on staff or parents. Although there is no conclusive evidence for reproductive, genetic, haematological, genetic, or fetal effects (Axelsson et al., 1996; Rowland et al., 1992; Sanders et al., 2008), exposure should be minimized: using occupational health and safety approved sedation rooms, maintaining an adequate patient face-to-mask seal and using a suitable scavenging system. Exposure to  $N_2O$  should be avoided during pregnancy.

## Ward management

*Patient-controlled analgesia* (PCA) delivery of opioids for alert, extubated patients over 7 years (McDonald and Cooper, 2001; Playfor et al., 2006) and *nurse-controlled analgesia* (NCA) (also described as continuous opioid infusions with nurse-initiated boluses) for younger patients, infants, and intubated patients (see Howard, Chapter 27, this volume) are universally used in the setting of major trauma/burns. These may be initiated in the ED and the patient continues to use this during their ward stay.

The most common opioid used is morphine but any opioid can be prescribed (Table 19.1). The usual prescription is for 1 to 2 ml boluses with a lockout of 5 to 7 min. Some institutions include a 1 or 4 h limit. In acute postoperative pain management, a background infusion on a PCA is generally avoided beyond 24 h (Howard, Chapter 27, this volume). In a trauma or a burn patient, a background is more often prescribed; when the continuous rate is higher than 2 ml/h, the bolus size is usually increased to match. An NCA involves the same concentration dilution infused at 0.5–4 ml/h with 1–2 ml boluses usually every 5 to 10 min.

Adjunctive *continuous ketamine infusion* (Howard, Chapter 27, this volume) is used frequently in these patients. Typical paediatric infusion prescriptions include ketamine 5 mg/kg in a total of 50 ml normal saline run at 0.1 to 0.3 mg/kg/h (1–3 ml per hour) (<[http://www.rch.org.au/anaes/pain\\_management/Ketamine\\_Infusion/](http://www.rch.org.au/anaes/pain_management/Ketamine_Infusion/)>). Higher infusion rates may be employed but hallucinations may occur (contributed to by polypharmacy, sepsis, and sleep deprivation). Our institution has infusion guidelines permitting additional ketamine bolus administration of 0.1 to 0.2 mg/kg every 30 min to be co-administered with opioid boluses or as an alternative if opioid side effects are prominent.

NSAIDs are particularly effective for pain of bony and muscular origin and may be used in the acute phase of analgesic management of musculoskeletal trauma and limb fractures, once volume resuscitation is complete, haemodynamic stability is achieved, and urine output is established (Anderson, Chapter 43, this volume). Parenteral forms are available. If NSAIDs are used when the patient is fasting or has an ileus, co-administration of a proton pump inhibitor is routine in moderate to severe burns or trauma patients

to reduce the combined effects of stress and NSAIDs on the gastric mucosa. NSAIDs also impair osteoclast activity. This is desirable to reduce heterotropic bone formation but undesirable in the setting of extensive bone graft/fusion procedures. Reduced fusion has been reported in adult studies using high-dose ketorolac but not with normal-dose short-duration exposure (Li et al., 2011) and not in a retrospective review of teenagers (Sucato et al., 2008).

The newer COX-2 *inhibiting agents* (Anderson, Chapter 43, this volume) available are IV parecoxib (a prodrug of valdecoxib) and oral valdecoxib in its own right. Oral celecoxib is in capsule form which may be challenging to administer to children. A suspension is stable (Donnelly et al., 2009) but has not been marketed. These agents are used off licence in children during or post surgery where bleeding is a concern and reduction or avoidance of opioid use is desirable, e.g. in patients with respiratory or neurological compromise or obstructive sleep apnoea. COX-2s are without the platelet inhibition effect but still share the NSAIDs' renal effects and are thus used post-stabilization in acute trauma and burns. They are employed in skin graft surgery, to reduce opioid requirement particularly when pruritis with burns is prominent, or for bone grafting surgery when the clinicians wish to avoid NSAIDs.

### Regional analgesia

Single-shot blocks performed in the ED can be repeated after ward admission and are employed perioperatively for these patients. Anaesthesiologists can offer *catheter techniques and local anaesthetic infusions* (see Zempsky, Chapter 47, this volume) (usually performed while anaesthetized) for internal fixation and limb reimplantation procedures of the upper (brachial plexus and interscalene techniques) and lower limbs (femoral and fascia iliaca), fractured ribs, flail segments, and thoracotomy (intercostal nerve blocks and paravertebral block/catheter) or for thoracic or abdominal surgery or lower limb fracture or graft surgery (epidural or caudal catheter/single shot). Other *perioperative single shot nerve blocks* employed are for free flaps and skin harvesting and/or grafting. These include lateral cutaneous nerve of thigh and transversus abdominis plane blocks and the aforementioned brachial plexus, femoral and fascia iliaca blocks (Sethna et al., Chapter 46, this volume).

### ICU analgesia-sedation practices

These patients are typically on opioids for prolonged periods. The commonly administered agents in ICU for analgesia and sedation management are the opioids morphine and fentanyl and the benzodiazepines midazolam and lorazepam (Playfor et al., 2006; Stoddard et al., 2011b; Tobias, 2005; Twite et al., 2004). A consensus guideline has been created in the UK for critically ill children (Playfor et al., 2006). It suggests:

- ◆ Morphine infusions of 10 to 60 mcg/kg/h.
- ◆ Fentanyl infusions of 4 to 10 mcg/kg/h.
- ◆ Midazolam 2 to 10 mcg/kg/min.

Ketamine is not mentioned in the 2006 UK consensus. It is used in Australian and US ICUs (Twite et al., 2004). In our experience this patient group requires high infusion rates, e.g. greater than 5 to 7 mcg/kg/min or 300 to 400 mcg/kg/h, while a US review reports the use as sole agent at high sedative doses of 1 to 2 mg/kg/h (Tobias, 2005). We typically co-administer ketamine, opioid, and benzodiazepine infusions in these patients when in ICU for days to weeks.

One Canadian article reports ketamine use for 37 days in a child (White and Karsli, 2007).

There is no consensus on the indications for muscle paralysis (Playfor et al., 2007). Muscle relaxant administration is generally reserved for trauma-burn patients with head injury, facial-airway-pulmonary burns, smoke inhalation and primary or secondary respiratory disease, dyssynchrony with the ventilator, or use of the less physiological ventilation techniques such as high-frequency oscillation. Higher-dose analgesic administration has resulted with the move away from prolonged muscle relaxant administration during prolonged ventilation (Playfor et al., 2007; Twite et al., 2004). The patients frequently develop polytolerance (Playfor et al., 2006). As a result, achieving adequate sedation levels can be challenging and the patient may resist mechanical ventilation and require physical restraint despite receiving high doses of multiple agents. Delirium and emergence phenomena are experienced and complicate the clinical assessment of pain, distress, and septic episodes (Playfor et al., 2006).

These patients commonly receive supplementation with alternative sedative agents (Playfor et al., 2006; Tobias, 2005; Twite et al., 2004) including antihistamines, chloral hydrate (25–100 mg/kg, 4–6/24), psychoactive agents (haloperidol, chlorpromazine, and more recently olanzapine (Stoddard et al., 2006)), propofol infusions 1 to 3 mg/kg/h for limited periods (with the clinicians being aware of propofol infusion syndrome) and alpha-2 agonists clonidine (transdermal, intermittent IV bolus doses 2–5 mcg/kg three times daily or infusion 0.1–2 mcg/kg/h) and more recently dexmedetomidine by IV/subcutaneous (SC) infusion at (0.1–2 mcg/kg/h with or without loading dose of 0.5–1 mcg/kg) (Lin et al., 2011; Phan and Nahata, 2008; Tobias, 2007, 2008; Walker et al., 2006). ICU staff may involve an acute pain service early or prior to discharge to the standard ward.

### Alpha-2 agonists

These agents have multiple desirable properties for use in burn or multitrauma patient management (Phan and Nahata, 2008). They are sedative, anxiolytic, reduce patient and distress, sympathetic outflow, and are adjunctive analgesics (Playfor et al., 2006). They are effective by reducing release of presynaptic catecholamines. The mechanism of analgesic effect is unclear with central (locus coeruleus) versus spinal (descending inhibition) versus peripheral effects (via substance P) proposed.

Clonidine causes a degree of bradycardia and hypotension which may be desirable in the polytolerant agitated patient but can be problematic during septic episodes. Interestingly in thermally injured rat studies, clonidine's vasoconstrictive effects were suggested to be detrimental by impairing healing (Cassuto et al., 2005b) and beneficial in terms of oedema reduction (Cassuto et al., 2005a). The bradycardic, hypotensive side effect also occurs with dexmedetomidine. Reports state it is well tolerated during sedation of the critically ill patient including paediatric cardiac or respiratory ICU patients (off-label use; Phan and Nahata, 2008; Tobias, 2007).

The doses for sedation are outlined in the 'ICU analgesia-sedation practices' section. Alpha-2 agonists are also useful premedicants prior to second-phase trauma or burns surgery: single-dose clonidine 2 to 5 mcg/kg orally or IV alone or combined with midazolam 0.5 mcg/kg oral or 0.1 mg/kg IV. Dexmedetomidine 2 mcg/kg has been used via the intranasal route and compared favourably to oral midazolam 0.5 mg/kg, as premedication prior to burns reconstructive surgery (Talon et al., 2009).

**Case example: trauma (continued)**

The 14-year-old train-surfer went to the operating room to have an intracranial pressure monitor placed and the right femoral fracture repaired with an internal fixation device. In the ICU she was sedated using morphine and midazolam infusions. After 24 h, sedation was stopped and she was extubated. She was neurologically normal but complained of severe left chest pain (rib fractures) and right thigh pain which was inadequately controlled with intermittent boluses of IV morphine. She was started on a PCA device with IV morphine and required this for 5 days. Her daily IV morphine consumption was 80 mg, 95 mg, 60 mg, 50 mg, and 40 mg respectively and so on day 6 she was converted to oxycodone CR and IR. She was still complaining of rib pain and disturbed sleep. She was prescribed OxyContin® 20 mg morning and 30mg at night and intermittent oxycodone IR 5 to 10 mg with amitriptyline 25 mg at night. She was discharged home on day 10 on OxyContin® 10 mg twice daily, oxycodone, ibuprofen, and amitriptyline 50 mg at night for review by her general practitioner.

**Case example: burns (continued)**

The ongoing pain of the 2-year-old boy with scald burns was treated with oral acetaminophen and oral oxycodone. The burns were debrided in theatre on three occasions including grafting under a general anaesthetic. He required regular burns dressing changes which were conducted on the ward in the burns bath and later at the bedside under IV ketamine.

## Step-down conversions from IV to oral opioids and tapering

The oral agent chosen and conversion plan in a burnt or multi-trauma patient will depend on the:

- ◆ Rate/total dose and duration of treatment with opioids.
- ◆ Presence of tolerance.
- ◆ Presence of ongoing pain sources.
- ◆ Degree of background pain.
- ◆ Breakthrough pain associated with care (turns, dressing changes, physiotherapy, surgery).
- ◆ Prevention of opioid withdrawal syndrome when pain is absent or controlled.
- ◆ Routes available (oral versus gastric or jejunal feeding tube).
- ◆ Timing of further interventions.

When the patient is still experiencing pain but is tolerating oral intake, the parenteral opioid dose received in the preceding 24 to 48 h is calculated. If greater than 0.5 mg/kg/day of IV morphine equivalent was received, then approximately 50% to 80% of this is given as long-acting (depending on pain severity) with an immediate-release opioid prescribed as a rescue either as a single dose (usually at one-sixth of the patient's overall use) or with a range to allow for fluctuations, e.g. pre-emptive administration prior to aggressive

physical therapy. The long-acting component is weaned when the patient requires less than two rescues a day. The drop in dose is usually 'convenient' according to the available tablet size. Usually the morning dose is reduced first as the patient can request rescue medication while awake during the day. The night dose is maintained to facilitate comfort in sleep and weaned and ceased last.

A proscription opioid taper is prescribed when pain is minimal and tolerance is present with little data to support practices (Fisher, 2010). Previously slow tapers were performed similar in length to the duration of the opioid treatment. More recent practice is to taper by 10% to 20% daily, ceasing in 5 to 10 days. When an IV is no longer required, patients are switched to the SC route or enteric administration of either a longer acting formulation (Anand et al., 2010) or a different opioid at equivalent dosing. Withdrawal symptoms are ideally scored 8-hourly using the withdrawal assessment tool (WAT)-1 (Franck et al., 2012) or modified Finnegan score (Oschman et al., 2011). Morphine sulphate sustained-release granules or methadone elixir are convenient for enteric tube administration. Treatment can be guided according to withdrawal score tiers and either non-taper performed if moderate symptoms persist or rescue doses of immediate release opioids (or benzodiazepines or alpha-2 agonists) prescribed if symptoms are severe.

Fentanyl patches can be used if the enteric route is unavailable. A pilot study reports the use of patches in patients treated with high cumulative doses of IV fentanyl. This study (Johnson et al., 2010) inappropriately employed the practice of partly covering a fentanyl patch with Tegaderm®. Twelve-microgram patches are now available (but use in non-cancer pain is still off-licence).

## Pruritis and neuropathic pain

Multitrauma patients experience neuropathic pain mechanistically related to their injury (e.g. compression or severance of peripheral nerves). They usually experience pruritis secondary to opioids. This is managed with antihistamines, optimization of non-opioid analgesics and opioid rotation, or small-dose naloxone (1 mcg/kg). Children and adult burns patients are frequently distressed by neurogenic pruritis (80–100% incidence). This is often severe, and persists for years after healing and successful grafting (Goutos et al., 2009, 2010). Neuropathic-like symptoms in the burn wound (hot sharp pain) are reported early from day 3 (Gray et al., 2011) and later (mean 4.3 months) post injury in adults (Schneider et al., 2006).

Agents used for pruritis in burns include antihistamines, topical doxepin or amitriptyline, massage therapy, topical treatments such as local anaesthetics, colloidal oatmeal, aloe vera and moisturizer, cool facewasher-icepack application, transcutaneous electrical nerve stimulation, compression garments, ondansetron and the gabapentinoids: gabapentin/pregabalin (Goutos et al., 2009). Five weeks of biweekly 15 min periburn massage sessions benefitted adolescents with burns with reduced pain, itching, and state anxiety versus controls (Parlak Gurol et al., 2010). Small open-label adult series of naltrexone (Jung et al., 2009; LaSalle et al., 2008) and IV lidocaine (Koppert et al., 2004) use have promise. More research is required to elucidate whether these agents or possibly clonidine could have beneficial roles if used early post injury.

The underlying mechanism of neurogenic itch and neuropathic pain-like symptoms probably has similar origin relating to C fibre in-growth, sprouting, increased spontaneous and high-frequency firing with stimuli, cross talk and descending inhibitory

dysregulation supported in rat nerve (Radtke et al., 2010) and adult human punch biopsy study (Hamed et al., 2011). Gabapentinoids are consequently used in both neuropathic itch and neuropathic pain management.

A paediatric pilot study of gabapentin use for itch reported doses of 5 mg/kg morning, lunchtime, and 5 then 10 mg/kg nightly (Mendham, 2004). Itch reduced after 24 h of therapy and antihistamine use reduced or ceased. A stepwise approach was adopted in two groups of 50 patients (25% children). Itch was relieved better in the polytherapy groups: gabapentin (5 mg/kg (maximum 300 mg) three times a day), cetirizine, cyproheptadine group (95%) versus the chlorpheniramine, cetirizine, cyproheptadine group (84%) versus monotherapy with gabapentin (10%) or chlorpheniramine (44%) (Goutos et al., 2010). Another adult trial of 28 days of monotherapy reports all 40 gabapentin-treated patients achieving itch-free status compared to only three cetirizine treated (Ahuja et al., 2011).

Pregabalin (75–300 mg twice daily) has to date been studied in adults only. Neuropathic pain scale sharp, hot, and itch scores were impacted as were procedural pain scores (Gray et al., 2011). Statistical significance was achieved although the clinical impact was relatively small.

Antidepressants are increasingly prescribed in US ICUs (Stoddard et al., 2006, 2011b) and elsewhere for burn (and multitrauma) patients. Early psychopathology is common and anxiety and depression can persist for months (van Baar et al., 2011). Antidepressant drugs are used for their antineuropathic, sedative, psychomodulatory, anxiolytic, and antidepressant effects (Stoddard et al., 2006). Antidepressant administration for paediatric neuropathic pain is sparsely studied with small sample sizes (see Rastogi and Campbell, Chapter 48, this volume). In a placebo-controlled crossover study, parents reported sertraline reduced post-traumatic stress symptoms without change in the children's report (Stoddard et al., 2011a). A placebo controlled trial in significantly burnt children suggests superiority of fluoxetine (72% response) versus imipramine (60%) and placebo (55%) (Robert et al., 2008). The same group published a chart review of the same agents (Tcheung et al., 2005) which was criticized for inadequate definition of acute stress disorder (Thombs et al., 2006).

The potential of antidepressant drug interactions must be carefully considered. Interactions can be both positive (e.g. adjuvant analgesia) and negative (CYP2D6 inhibition, serotonergic syndrome, e.g. with co-administration of tramadol).

## Sleep disturbance

Most hospitalized patients have sleep disturbance which is more prominent in trauma and burns patients. Sleep deprivation results from multiple factors (Jaffe and Patterson, 2004):

- ◆ Physiological effects of trauma or burns with stress response, reduced growth hormone production, and fluid retention (exacerbation of obstructive sleep apnoea).
- ◆ Psychological effects—post-traumatic stress symptoms and disorder, anxiety and depression, distressing repeated procedures.
- ◆ Presence of prolonged periods of pain or pruritis.
- ◆ Treatment interventions such as frequent observation, sedative-analgesic administration that affect slow wave sleep (SWS) and rapid eye movement (REM) sleep, pharyngeal motility, and cause hypoventilation (opioids, benzodiazepines, barbiturates).

- ◆ Disrupted circadian rhythm, un-conducive environment (noise, light).

Non-pharmacological techniques are important and should be instituted as early as permissible in the unwell patient:

- ◆ Improve sleep hygiene (regular to bed and planned waking times), restrict napping, exercise during day.
- ◆ Light therapy: UV exposure, dawn simulation.
- ◆ Reduce stimuli: restrict visitors, reduce noise, stop TV/gaming.
- ◆ Nutritional: avoid caffeine and heavy evening meal.
- ◆ Relaxation training.

Pharmacological agents are introduced to restore the sleep wake cycle. They are commenced as early as feasible and include:

- ◆ Various benzodiazepines orally (PO)/IV or alternative BDZ receptor agonist (zolpidem: PO). These reduce sleep latency but negatively affect SWS/REM sleep and have rebound insomnia on cessation.
- ◆ Melatonin at doses of 0.5 escalating to 1.5 mg/kg PO. This agent should probably be first line in these patients as not only is it chronobiotic but it is a free radical scavenger, an antioxidant, reduces pro-inflammatory cytokines and adhesion molecules and may reduce thermal injury-related lymphocytopenia and oxidative damage (Maldonado et al., 2007). In rats at high dose (10 mg/kg), it reduces inflammatory marker elevation and coagulation disorder (Bekyarova et al., 2010) and gastric mucosal injury (Bekyarova et al., 2009).
- ◆ Haloperidol, particularly if delirium is present—0.1 mg/kg PO or 0.02 mg/kg IV.
- ◆ Sedative antihistamines—promethazine, chlorpromazine, etc. which may assist with pruritis but are simultaneously detrimental to sleep architecture.
- ◆ Clonidine 3 to 5 mcg/kg for sedative and anxiolytic properties.
- ◆ Antidepressants with sedative side effects: amitriptyline/nortriptyline 0.5 escalated to 1.5 to 2 mg/kg PO versus treatment of anxiety or depressive disorder with a morning SSRI, e.g. fluoxetine 5 to 20 mg.
- ◆ Gabapentinoids can be administered at higher evening versus morning doses and will assist pain, pruritis, anxiety, and cause sedation.

## Procedural interventions

General anaesthesia, the performance of local anaesthetic blocks intraoperatively, and postoperative parenteral analgesic techniques are discussed elsewhere in this volume.

Procedures are often performed in the ward and later in the outpatient environment. During sedation-analgesia for a surgical intervention, opportunity can be taken for additional interventions such as IV or arterial line re-siting or dressing change, passive physical therapy, and naso-jejunal feeding tube insertion.

Techniques available to the patient during ward procedures include the following:

*Propofol IV* for light or deep sedation for ward procedures alone and in combination with opioids or ketamine. A study of paediatric burns dressing changes (n = 32) showed equal efficacy of IV propofol-fentanyl (1.2 mg: 1 mcg/kg) and propofol-ketamine (1.2 mg: 1 mg/kg) with less restlessness in the propofol-ketamine group (Tosun et al., 2008).

*Ketamine* is frequently used as a sole agent for burns dressing changes and burns baths. It can be given via various routes: intranasal, oral (0.5–2 mg/kg for analgesia and 5–7 mg/kg for sedation), and IV (0.5–2 mg/kg) in titrated boluses. Ketamine (and its active metabolite norketamine) pharmacokinetics have been studied in paediatric burns patients having general anaesthesia. Pharmacokinetic parameters were similar to those in paediatric ED fracture patients (Brunette et al., 2011). Simulation dosing data suggests 10 mg/kg orally followed by infusion of 1 mg/kg/h permits short-duration surgical dressing at 45 min. A large retrospective review reports protocolized IV ketamine administration (in conjunction with IV or oral midazolam) by nurse practitioners (Owens et al., 2006). Mean ketamine doses of 147 mg IV were given to children of mean weight 30 kg having 347 bedside procedures. Ten events (2.9%) required respiratory intervention: repositioning (2), oral airway insertion (1), supplemental oxygen via nasal prongs (1) and bag-mask ventilation (4) with none requiring intubation. Rectal S-ketamine 0.75 mg/kg in combination with midazolam 0.4 mg/kg is reported for 47 outpatient dressing changes in 30 young children with 5% to 15% burns. Sedation was good to excellent in the majority (Heinrich et al., 2004).

N<sub>2</sub>O alone is a popular inhaled analgesic management option during in and outpatient procedures (e.g. external fixateur adjustments) or dressing change. It can be used in conjunction with timely administration of IV, IN, and oral opioids and non-opioids or midazolam.

*Single-dose benzodiazepine* via various routes is useful for procedural sedation: midazolam providing amnesia and lorazepam and diazepam used for longer-duration anxiolysis-sedation.

*Oral analgesic-sedative combinations* for dressing changes include acetaminophen with a NSAID, opioid, and a benzodiazepine or clonidine and/or ketamine.

*Non-pharmacological therapies* include relaxation training, hypnosis, massage, and various forms of distraction therapy including music, play (including clown doctors), art, schooling, cartoon and favourite video/DVD viewing, hypnosis, massage, pet therapy, interactive videogames and virtual reality.

### Interactive video games (IVGs) and virtual reality (VR)

IVGs have been studied in burns patients. Nintendo Wii® has been compared with Play station Eye Toy®. The latter was associated with higher demands and longer duration of active upper extremity motion indicating potential application in (post-burns) rehabilitation (Parry et al., 2012). *Immersive VR* involving a computer-generated virtual environment has been employed for painful physiotherapy. The patient wears head gear to exclude visual and aural input of their medical intervention (Sharar et al., 2007). In adult and paediatric burn patients, worst pain intensity, pain unpleasantness, and time spent thinking about pain are reduced (Sharar et al., 2007). Multiple use of immersive VR was assessed in children: pain scores were reduced and affect improved with patients experiencing fun although there was no difference in the maximum range of motion achieved (Schmitt et al., 2011).

For outpatient dressing changes, standard distraction (access to TV, video games, stories, toys, nursing staff soothing, and care giver support) was compared to multimodal distraction (MMD) involving a device that includes a procedural preparation video ('Bobby got a Burn') and includes games, 'touch and find' stories with multisensory feedback (visual, auditory, and vibratory). Parent and nursing

pain scores were significantly less in the MMD group (reduced by 30% and 50% respectively; Miller et al., 2010). Virtual reality has been employed in a patient series (aged 9–40 years) having debridement in the hydrotank (burns bath; Hoffman et al., 2008).

### Key recommendations

- ♦ Pain management in trauma and burns patients should be embedded in a standardized approach to trauma care.
- ♦ Opioid use is the mainstay of therapy and where possible opioid-sparing adjuvant agents should be introduced.
- ♦ Intranasal fentanyl is a novel administration technique that has efficacy in the pre-hospital and ED setting for trauma patients. Its use is likely to extend to ward and outpatient settings for this patient group.
- ♦ Local anaesthetic agents either topically, by infiltration, or as a nerve or regional block should be employed wherever possible to reduce the need for systemic agents (particularly opioids) and their subsequent systemic side effects.
- ♦ Multimodal analgesia is essential in the effective management of pain in moderate to severe multitrauma or burn patients. Evidence supporting this practice in paediatrics is sparse.
- ♦ Polypharmacy leads to polytolerance; withdrawal scoring should be a routine assessment performed in these patients during down-titration of opioids and sedatives.
- ♦ Ketamine is useful as an analgesic and in anaesthetic doses for procedural sedation.
- ♦ Alpha-2 agonists have multiple properties of therapeutic benefit in this patient group. The reported negative effects of clonidine in thermally injured rats need to be clarified as off-licence use of dexmedetomidine in this paediatric patient population is increasing. Both clonidine and dexmedetomidine offer advantages in sedation of these patients, and abstinence syndrome prevention and treatment.
- ♦ Scientific understanding of the neurobiology of pain and the response to thermal injury at cellular, nerve fibre and tissue level is progressing.
- ♦ Gabapentinoids offer benefits in neuropathic pain symptoms and pruritis. A multimodal approach is likely to be of benefit in these two conditions over mono-therapy alone.
- ♦ Depression and anxiety symptoms are prominent several months to years post multitrauma or burn event. Antidepressant therapy should be considered early along with psychology/counselling to simultaneously address insomnia, neuropathic pain, pruritis, anxiety, depression, and post-traumatic and current stress.
- ♦ Intervention to improve sleep should be employed as early as feasible. More study on the benefits of therapy with melatonin is required.

# CHAPTER 19

## Needle procedures

Anna Taddio

### Summary

All children undergo needle procedures as part of routine medical care. Numerous interventions are available for relieving pain from needle procedures. These interventions can be divided into four domains (4 Ps of pain management): procedural, pharmacological, psychological, and physical. Treating needle pain reduces pain and distress and improves satisfaction with medical care. Other potential benefits include a reduction in the development of needle fear and subsequent health care avoidance behaviour. Adoption of the 4Ps into routine clinical practice is feasible and should become a standard of care in the delivery of health care for children. This chapter is a narrative review of the current knowledge about: epidemiology, pain experience, practices and attitudes, and evidence-based interventions for pain management during common needle procedures.

### Introduction

Despite their vital importance, needles are regarded as the negative symbol of health care (Schechter, 2006). This is because they cause anticipatory anxiety and pain. The needle is particularly concerning to children, who regard any procedure involving a needle as one of the most frightening and painful health-related events.

### Epidemiology of needle procedures

Injections, venepunctures, and venous cannulations are among the most prevalent needle procedures undertaken in children and are the focus of this chapter. Injections consist primarily of intramuscular or subcutaneous administration of vaccines, and are experienced repeatedly throughout the lifespan. In the US, healthy children undergo over four dozen separate vaccine injections by the time they are adults (<<http://www.immunize.org/catg.d/p4050.pdf>>). Venepunctures and venous cannulations are the most common sources of needle pain for hospitalized children (Ellis et al., 2002; MacLean et al., 2007; Stevens et al., 2011; Zhu et al., 2012). In one study, venepuncture and venous cannulation accounted for almost two needle procedures per day among neonates in the first week of life (Stevens et al., 2003). In another study including hospitalized children of all ages, the mean frequency of all common needle procedures together was one every other day (Stevens et al., 2011).

### Clinical impact of needle procedures

Although needle procedures are generally regarded as a source of 'mild' acute pain, there is substantial variability in the level of pain

reported by different individuals. In general, children report needle procedures as being more painful than adults do (Goodenough et al., 2008; Schneider and LoBiondo-Wood, 1992) and regard any procedure involving a needle as one of the most frightening and painful health-related events (Cummings et al., 1996; Ellis et al., 2004; Humphrey, 1992). The majority of young children exhibit moderate-severe distress during needle procedures (wherein distress encompasses the combined effects of anxiety and pain). Since current methods of pain assessment do not allow pain to be differentiated from anxiety, pain responses in young children include anxiety responses as well. In one study of immunization injections, over 90% of children aged 15 to 18 months and 45% of those aged 4 to 6 years were seriously distressed (Jacobson et al., 2001). In two separate studies of venepuncture, 64% of 3 to 6-year-olds (Fradet et al., 1990) and 83% of 2½- to 6-year-olds (Humphrey et al., 1992) had high distress. The percentage with high distress decreased with increasing age: 51% and 28% for 7 to 12 years and 12 years and greater, respectively (Humphrey et al., 1992).

Needle procedures undertaken in infancy and childhood may impact on how pain is perceived in the future by altering the normal development of pain processing pathways (Fitzgerald and Walker, 2009) or by leading to the development of needle fears (Bijttebier and Vertommen, 1998; Chen et al., 2000; Jacobson et al., 2001; Rocha et al., 2003). Increased level of fearfulness, lower sense of control over health, and distrust of adults, particularly health providers, can occur after experience with repeated needle procedures in childhood as well (Rennick et al., 2002; Salmela et al., 2011) and such procedures may be perceived as more traumatic than the underlying disease (Hedstrom et al., 2003; Ljungman et al., 1999).

Recent studies demonstrate that about two-thirds of children have a fear of needles (Taddio et al., 2012c; <<http://www.painfoundation.org/media/resources/pain-surveys.html>>). Needle fears may be carried into adulthood whereby it is estimated that about one-quarter of adults are afraid (Taddio et al., 2012b) and one in ten have an outright phobia (Hamilton 1995). These fears place individuals at risk for adverse health and lifestyle consequences (Sokolowski et al., 2010). Individuals demonstrate health avoidance behaviours, including abstinence from: preventive health measures (e.g. immunizations, dental visits; Johnson et al., 2008; Sokolowski et al., 2010; Wright et al., 2009) and treatment interventions, even life-saving ones (e.g. diabetes management; Howe et al., 2011). Refusal of needle procedures can lead to social and legal consequences as well, including refused travel, education, employment, marriage, or

pregnancy (Sokolowski et al., 2010). Reduced herd immunity from low immunization compliance rates may lead to outbreaks of vaccine-preventable diseases (Diekema, 2012; Omer et al., 2009).

Needle procedures carried out in children are also concerning for parents and clinicians. Alterations in physiological parameters (blood pressure, heart rate) and increased anxiety are documented for parents of children undergoing needle procedures (Smith et al., 2007). Both parents and clinicians report non-compliance with immunization in an effort to reduce pain in children (Harrington et al., 2000; Madlon-Kay and Harper, 1994; Woodin et al., 1995).

## Pain management practices and attitudes

Historically, there has been under-utilization of pain-relieving interventions for needle procedures performed in children. Several audits conducted over the last decade reveal wide variations in practices (Carbajal et al., 2008; Ellis et al., 2002; Johnston et al., 2011; MacLean et al., 2007; Simons et al., 2003; Stevens et al., 2003; Chan et al., 2013; Zhu et al., 2012). Studies in hospitalized children, for instance, document pain-relieving interventions in 0% to 90% of needle procedures. Studies in neonates report higher utilization rates than those involving all ages of children. Intramuscular or subcutaneous injections are associated with higher utilization rates than venepuncture and venous cannulation. In one study comparing two time points, a lower number of procedures were documented in the more recent time period, suggesting a reduction in the burden of pain over time in hospitalized infants (Johnston et al., 2011). This finding contrasts with the outpatient setting, where the burden of pain has been steadily increasing over time due to the continual increase in the number of vaccines being introduced into routine clinical practice.

Taking care of a child's pain is important to parents (Ammentorp et al., 2005). Parents are prepared to wait longer and to pay to reduce their child's pain (Meyerhoff et al., 2001; Myrick and Barfield 2006; Walsh and Bartfield 2006; Wasserfallen et al., 2006). Clinicians regard pain management as the parents' responsibility. They focus on the technical aspects of a child's medical care, forgoing children's (and parents') experiences of that care, including associated pain. With respect to needle procedures, clinicians often hold a procedure-focused, rather than child-focused view, and dismiss concerns about pain by describing it as a self-limited process. Dismissive attitudes about pain in clinicians results in parental acceptance of pain as 'the necessary evil' that must be traded-off to obtain good health in their children (Parvez et al., 2010).

Since parents value pain management and pain management improves the quality of care that is delivered, it follows that the societal value of pain management is high. Pain management should thus be incorporated within the process of all needle procedures (Wasserfallen et al., 2006). Parents, health care providers, and institutions must partner together to address barriers to best practices. The model of family-centred care may serve as a theoretical framework for this partnership (Franck and Callery, 2004). Briefly, this model describes participation of the family in children's health care and in decision-making in order to achieve optimal health care delivery in children.

## Evidence-based interventions for pain management

There are numerous effective, safe, and feasible interventions for managing pain from needle procedures. These interventions

can be categorized into four domains: 'Procedural' techniques that operators can use when performing the procedure; and 'Pharmacological', 'Psychological', and 'Physical' techniques that parents, operators, and children can use to modify the experience of pain for children; herein referred to as the '4 Ps' of pain management. The remainder of this chapter reviews examples of interventions within these domains. Figure 19.1 illustrates the timeline for their use to mitigate pain from needle procedures undertaken in children. Systemic analgesics and adjuvant interventions are reviewed separately, in chapters in Section 6.

### Procedural interventions

The best way to manage pain is to avoid it. Use of non-invasive technology is one way of avoiding pain—for instance, needle-free immunization (e.g. intranasal influenza vaccine) or non-invasive sampling devices (e.g. transcutaneous bilirubinometry; Yap et al., 2004). Children should undergo the minimum number of procedures possible. This is particularly important for hospitalized children, who frequently undergo unnecessary procedures due to lack of communication and coordination among hospital personnel. For children requiring ongoing or repeated intravenous access, long-term indwelling catheters can be inserted. With respect to injections, combination vaccines can be used rather than single-antigen ones to minimize the number of separate injections (Zareba, 2006).

Health care providers undertaking needle procedures can utilize a variety of approaches to mitigate pain, including selecting one particular procedure over another and using specific techniques to carry out a procedure. For example, blood sampling can be performed using venepuncture instead of heel lance (Shah and Ohlsson, 2011). For intramuscular immunization injections, injections can be carried out quickly without prior aspiration (Taddio et al., 2009a). When multiple injections are being given sequentially, pain can be reduced if the most painful one is administered last (Taddio et al., 2009a).

Since the physicochemical properties of the injectate can also influence pain, efforts should be made to administer the least painful formulation of a medication. In separate systematic reviews, pain from lidocaine infiltration (Cepeda et al., 2010) and measles-mumps-rubella vaccine injection (Taddio et al., 2009a) were reduced when a more physiological pH formulation was used. Such buffered lidocaine solutions, however, are not commercially available as they are not stable. They can be compounded prior to injection by adding 1 ml of sodium bicarbonate 8.4% to 9 ml of lidocaine 1% (Cepeda et al., 2010). Buffering is not recommended for vaccines as the effect on immunogenicity is not known.

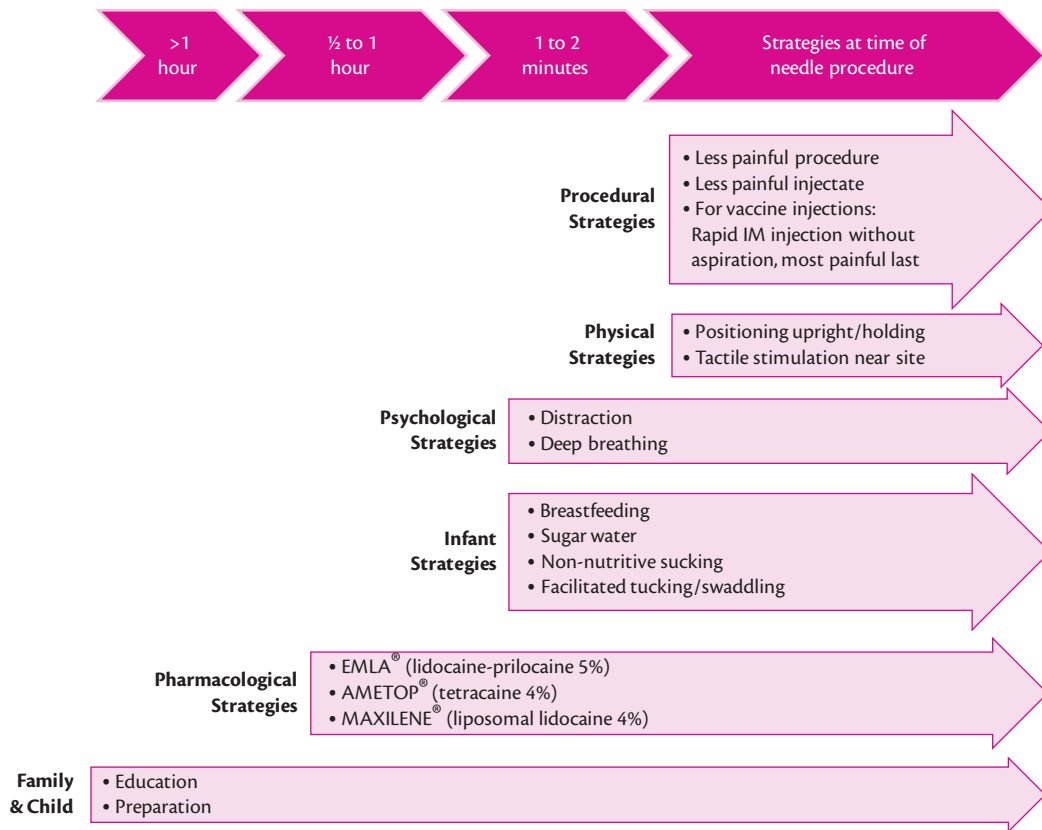

The temperature of the injectate may also affect pain. Lidocaine solutions that are warmed to body temperature, for example, cause less pain during infiltration, even if the lidocaine is buffered (Hogan et al., 2011b). No benefit has been observed for warmed vaccines, and thus, is not recommended for vaccinations (Taddio et al., 2009a).

### Pharmacological interventions

A variety of pharmacological interventions are available for reducing pain from needle procedures. The most common are local anaesthetics and sweet solutions.

#### Local anaesthetics

Local anaesthetics are the most studied class of pharmacological interventions for reducing pain from needle procedures in children.

**Figure 19.1** Timeline for pain relieving strategies prior to and during needle procedures: procedural, physical, psychological, and pharmacological strategies (plus infant and family/child). IM = intramuscular.

Local anaesthetics provide analgesia by blocking nociceptive transmission in nerve cells. They are administered to the site of the needle procedure using non-invasive (i.e. topical) and invasive (i.e. needle) methods.

Table 19.1 summarizes currently marketed products that are applied topically on intact skin and rely on passive diffusion to achieve dermal anaesthesia. Depending on the product, clinically reliable local anaesthesia is achieved after a contact time of 20 to 60 min. Commercial preparations available in a disc/patch formulation have the local anaesthetic embedded within the delivery system and are adhered to the skin. Other preparations require that the appropriate dosage (usually about 1 g) be applied to the skin in a mound, and then covered with an occlusive dressing. Occlusion facilitates absorption of the anaesthetic and prevents accidental removal and/or ingestion. It may be necessary to apply topical anaesthetics to more than one body region (or site) to account for multiple procedures. Care must be taken, however, to ensure that maximum recommended dosages are not exceeded in order to prevent systemic toxicity.

Needle procedures are usually undertaken right after the required contact time has been met and both the dressing and anaesthetic have been removed. If a procedure is not undertaken immediately, a non-toxic marker can be used to mark the site where the anaesthetic was applied—this prevents subsequent needle puncture in an unanaesthetized area. Attention should be given to the elapsed time following removal, as the anaesthetic effect will begin to fade thereafter. Elapsed times of more than 1 h are not generally recommended in order to minimize the risk of analgesic failure.

**Table 19.1** Commercially available topical anaesthetics

Topical anaesthetic	Availability	Recommended application duration in minutes
Lidocaine 2.5%—prilocaine 2.5%	Cream, patch	60
Lidocaine 7%—tetracaine 7%	Heat delivery patch	20
Liposomal lidocaine 4%	Cream	30
Tetracaine 4%	Gel	40

Multiple systematic reviews and meta-analyses have concluded that local anaesthetics are effective and safe for reducing pain from common needle procedures (Fetzer, 2002; Lander et al., 2006; Shah et al., 2009) (see also Zemspky, Chapter 47, this volume). There is evidence that they may improve procedure success rate (e.g. insertion of indwelling cannula or procurement of blood sample is achieved on the first attempt) and reduce total procedure duration time as well, presumably due to reduced pain and movement during procedures (Taddio et al., 2005b). One meta-analysis found tetracaine to be superior to lidocaine-prilocaine for reducing pain from venepuncture (Lander et al., 2006), suggesting that not all preparations are equianalgesic. No differences, however, have been observed in procedural success rate among various preparations (Arendts et al., 2008).

Despite their demonstrated effectiveness, topical anaesthetics are under-utilized for needle procedures. This is due, at least in part, to perceptions about their effectiveness and feasibility. There is an expectation that topical anaesthetics will lead to painless needle procedures. However, this is not usually the case. Pain perception is complex, and a result of multiple interacting factors including anxiety and fear, which topical anaesthetics may not eliminate. In addition, anaesthetics do not block all sensation—sensations of pressure are still present, which may be interpreted by children and/or adults as pain. The depth of penetration is several millimetres, resulting in partial blockade of nociceptive input for most procedures. Finally, the presence of genetic polymorphisms may predispose some children to analgesic failure (Kleiber et al., 2007).

Another barrier to the use of topical anaesthetics relates to perceptions of feasibility. The requisite waiting time makes it impossible to use topical anaesthetics for emergency procedures. Most needle procedures, however, are not required on an urgent basis. Studies performed in a wide variety of clinical settings demonstrate that topical anaesthetics can be incorporated within usual waiting times for most needle procedures (Fein, 1999; MacLean et al., 2007; Robieux et al., 1990; Taddio et al., 2012a). The person applying the preparation must also know where to apply the topical anaesthetic. Concerns that parents are unable to apply topical anaesthetics to the appropriate site(s) are unsupported by primary research (Koh et al., 1999; Taddio et al., 1994).

Topical anaesthetics are well tolerated and considered safe in most children. When used for immunization, they do not appear to interfere with antibody response (Shah et al., 2009). Systemic toxicities have been reported rarely and have included seizures, dysrhythmias, and methaemoglobinaemia. Methaemoglobinaemia is a toxicity of lidocaine-prilocaine, owing to the oxidizing effects of metabolites of prilocaine. Neonates and young infants are more susceptible because of immature enzyme activity. For the most part systemic toxicities have only occurred after either excessive doses or durations of application were used. Careful attention to dose and duration of application are required to minimize significant absorption and systemic effects (Shachor-Meyouhas et al., 2008).

Transient local side effects are relatively common—they occur in one-quarter to one-half of individuals, and include transient skin colour changes (erythema, blanching), oedema, and itching. Allergic contact dermatitis is uncommon or rare, and may be more likely with ester-based topical anaesthetics (tetracaine; Shah et al., 2009).

To reduce the onset of action of topical anaesthetics and increase the depth of penetration of the active agent, alternative methods of administration have been used. Of these, injection of local anaesthetics is the oldest and most common method currently in use. Typically, small volumes (0.1–0.3 ml) of lidocaine 1% solution are injected intradermally or subcutaneously using a narrow-gauge (27 or 30) needle (Klein et al., 1995; Luhmann et al., 2004; Soliman et al., 1988). The onset of anaesthesia is approximately 1 to 3 min.

There is reluctance about using lidocaine injection in some clinical settings. This is not surprising, given its administration is associated with an additional needle puncture, and pain from the needle puncture and the lidocaine itself (which causes a burning/stinging sensation). It should be noted however, that the pain from lidocaine injection is less than that from the needle procedure for which it is being utilized; hence, there is an overall net benefit of less pain when lidocaine injection is used for needle procedures. Nevertheless, when lidocaine injection is utilized, it should be

accompanied by strategies to reduce injection pain, including: buffering lidocaine with sodium bicarbonate (Cepeda et al., 2010) and warming the solution to body temperature (Hogan et al., 2011b).

More recently, novel technologies have been developed that allow for rapid administration of local anaesthetics without the need for needle puncture (Zempsky, 2008). For the most part, there is very limited experience with these technologies and they are not readily available in most clinical settings. These technologies offer alternative methods of administering local anaesthetics and may come to have an important role in the management of cutaneous pain in children in the future. They are discussed in further detail by Zempsky (Chapter 47, this volume).

With so many options available, the choice of which local anaesthetic administration method to use depends primarily on: urgency of procedure, procedure site, child factors, availability of equipment, and availability of experienced staff. If procedures are required urgently, only techniques with a short onset of action are suitable. For topical preparations, disc/patch dosage modalities may be more convenient to use provided that the contact surface area and geography of body region allow them to be suitably applied. The presence of specific child factors, such as age, distress levels, allergies, or child preferences lend themselves to the selection of certain preparations over others. Finally, the presence of requisite equipment and trained staff are needed to administer them.

### Sweet solutions

Sweet solutions have analgesic effects in infants up to 12 months of age (Gaspardo et al., 2005; Harrison et al., 2010; Shah et al., 2009; Stevens et al., 2010). Their mechanism of action is unknown; however, it has been speculated to involve taste-induced release of endogenous opioids, calming through non-nutritive sucking, and/or distraction. There are a plethora of studies showing reduced pain behaviours in infants given sweet solutions while undergoing needle procedures (reviewed in detail by Harrison et al., Chapter 49, this volume). Of note, a recent study failed to demonstrate an effect on pain-specific brain activity (Slater et al., 2010), questioning whether sweet solutions are ‘true analgesics’. However, at present, the clinical significance of that study is not known.

A variety of natural and artificial sweet compounds have been evaluated; the most widely used is sucrose (Taddio et al., 2009b). Sucrose solutions are administered on the infant’s tongue with a pacifier, syringe, or cup. Administration with a pacifier stimulates non-nutritive sucking and may improve effectiveness (Buscemi et al., 2008; Stevens et al., 2010). The onset of action is fast (within 10 sec), with a peak effect at 2 min, and duration of action of up to 10 min (Buscemi et al., 2008). The usual single dose is 0.5 to 2 ml of 12% to 24% strength (weight/volume; Stevens et al., 2010). Multiple-dose regimens utilize lower single doses, particularly in preterm infants (Stevens et al., 2010) owing to concerns about potential adverse effects. It is not clear whether there is a dose-response effect (Harrison et al., 2010; Stevens et al., 1997).

Sucrose is well tolerated—adverse effects are rare and transient, including choking and oxygen desaturation (Stevens et al., 2010; Taddio et al., 2008). One multiple dose study in preterm infants, however, suggested worse neurobehavioural development and severity of illness scores at selected follow-up testing ages with increasing sucrose exposure (Johnston et al., 2002)—the significance of this finding is unknown (see Harrison et al., Chapter 49, this volume, for a more detailed review).

## Psychological interventions

Psychological interventions include cognitive and behavioural techniques aimed at reducing child anxiety and pain. The proposed mechanism of action is hypothesized to involve the ‘gate control theory’ of pain, whereby descending nerve signals involving thoughts, beliefs, emotion, and attention modulate ascending pain signals (Cohen 2008; Schechter et al., 2007).

For the most part, psychological interventions do not require specialized equipment, and are devoid of toxicity. However, their effectiveness often hedges on the competence of individuals delivering them. Parents and clinicians may not be adequately trained, resulting in limited success.

## Preparation of parents and children

Having parents present during needle procedures undertaken in children is consistent with parent and child preferences and hence, supports family-centred care (Gonzalez et al., 1989; Piira et al., 2005; Pruitt et al., 2008; Ross and Ross 1984; Stephens et al., 1999). Parental presence has the added benefit of promoting respect for the child’s emotional welfare. Two separate studies correlated parental presence with enhanced use of pain strategies in hospitalized infants (Carbajal et al., 2008; Johnston et al., 2011), either because parents request pain-relieving interventions or their presence prompts clinicians to administer them (Carbajal et al., 2008; Johnston et al., 2011).

Parent behaviour significantly influences child distress and pain during needle procedures, both positively and negatively (Blount et al., 2001; Cohen et al., 2002; Frank et al., 1995; Gonzalez et al., 1993; Liossi et al., 2007; Rocha et al., 2003; Sweet and McGrath, 1998). Parents should therefore be targeted for education about strategies that reduce a child’s distress and pain (Cohen, 2008). In general, children’s distress responses are reduced when adults are calm and use *coping-promoting* strategies such as coaching children to cope and distracting children (diverting children’s attention away from the procedure). Conversely, responses are increased when adults are anxious and use *distress-promoting* strategies such as apologizing, criticizing, reassuring, or empathizing. The latter may focus children’s attention on the procedure by their nature and the manner in which they are communicated.

Children should be prepared for needle procedures ahead of time as prior preparation helps to reduce an individual’s anxiety and pain perception (Jaaniste et al., 2007; Suls and Wan 1989). Preparation includes developmentally-appropriate explanations of procedural and sensory information, including: what will happen, how it will feel, what will be done to prevent discomfort, and what children can do to help (Schechter et al., 2007). It may also involve demonstrations and/or practice opportunities. Children should not be told ‘it won’t hurt’—this is an ineffective strategy and promotes distrust (Taddio et al., 2010a).

In general, preparation should not be performed too far in advance—this may cause children to become fixated on the event and become more anxious, or to forget procedure details (Cohen 2008). Children should have enough time to process the information and plan how they will cope. The information can be presented the day prior to or on the day of the procedure depending on the individual child (Cohen, 2008). Preparation may be suitable commencing at age greater than 2 years (Schechter et al., 2007); however, it may have greater benefit in children 7 years and older (Cohen, 2008).

## Distraction

Distraction involves any technique that removes a child’s attention from the needle procedure to something more pleasant. It is viewed as a key non-pharmacological intervention for essentially all ages of children. Multiple reviews and meta-analyses demonstrate the effectiveness of distraction for reducing pain during needle procedures (Chambers et al., 2009; DeMore and Cohen, 2005; Kleiber and Harper, 1999; Richardson et al., 2006; Uman et al., 2006) (see also Cohen et al., Chapter 53, this volume). Distraction is usually commenced before the procedure begins, and is continued during and afterwards—this helps reduce anticipatory anxiety and pain, and enhances recovery (Cohen, 2008).

Distraction interventions typically use a combination of cognitive and behavioural approaches. They can consist of relatively simple, cost-neutral or low-cost techniques, such as non-procedural talk, breathing exercises, bubble blowing, playing with toys/games, and watching movies. Alternatively, they can involve more complex and cognitively-based interventions such as hypnosis (Buscemi et al., 2008). The time required to teach an individual to use simple distractions is short (up to 15 min), making it feasible for most clinical settings (DeMore and Cohen, 2005). Cognitively-based interventions, however, usually require facilitation by a trained individual such as a child life specialist, hence, are not easily implemented. In addition, cognitive interventions can realistically only be used in children aged 3 years and older (Richardson et al., 2006).

The most effective distractors stimulate multiple sensory modalities (e.g. vision, hearing, touch), elicit positive affective states (e.g. laughing), or require overt behavioural responses (Cohen, 2008; DeMore and Cohen, 2005). The critical aspect for any distractor, however, is that a child is actively engaged in it—otherwise, it will be ineffective. To this end, it is important to select age-appropriate and engaging distractions (Schechter et al., 2007). Facilitation, either from a health provider or parent is also important, in order to ensure the child’s attention is maintained on the distraction (Cohen, 2008; DeMore and Cohen, 2005).

For infants, the proposed primary methods of distraction include parental use of coping-promoting behaviours and physical interventions (Schechter, 2006) rather than the use of external items (e.g. toys, books). A recent systematic review and meta-analysis found insufficient evidence to recommend toy-mediated distraction in infants and young children (up to 3 years; Pillai Riddell et al., 2011). The same review, however, found sufficient evidence of effectiveness for video-mediated distraction in the same population (Pillai Riddell et al., 2011). Some of the observed inconsistencies in the overall effectiveness of distraction may be explained by who delivers the distraction (clinicians versus parents; Chambers et al., 2009). Parents may be less effective than clinicians because they are: (1) insufficiently trained or experienced to administer distraction, (2) unable to undertake other soothing behaviours while performing distraction, or (3) anxious and transmit their anxiety to children.

## Physical interventions

Physical interventions target body position and physical activity. They are generally cost-neutral. Numerous physical interventions have been shown to reduce pain responses in infants and children undergoing needle procedures.

## Breastfeeding for infants

Breastfeeding reduces pain responses in infants up to 1 year of age (Shah et al., 2007, 2009). Although categorized as a physical pain-relieving intervention, the analgesic effects of breast milk are hypothesized to be mediated by multiple mechanisms, including touch/maternal presence (skin-to-skin contact), non-nutritive sucking, sweet-taste and other potentially analgesic substances, and smell. Compared to other pain-relieving strategies such as sweet-tasting substances and local anaesthetics, breastfeeding offers a natural, cost-neutral, and convenient option. Breastfeeding is commenced before the needle puncture and continued throughout the procedure and afterward. Thus, an adequate latch must be established *prior* to the procedure commencing—this may take a few minutes.

Concerns have been raised about the potential for breastfeeding analgesia to cause infants to choke. To date, this adverse effect has not been documented. Another concern is that infants might learn to associate breastfeeding with pain, which will negatively impact on future breastfeeding. This adverse effect is also unlikely as needle procedures are sporadic; hence, breastfeeding would not be a reliable cue for an impending painful procedure (Shah et al., 2009).

## Other physical interventions for infants and young children

A variety of physical interventions have been evaluated for their effectiveness in infants and young children undergoing painful medical procedures, including skin-to-skin contact (also called kangaroo care/kangaroo-mother care), non-nutritive sucking, rocking, and swaddling (Pillai Riddell et al., 2011; Taddio et al., 2009a; van Sleuwen et al., 2007).

Skin-to-skin contact involves holding infants clad only in a nappy against the bare skin of a parent. In a recent systematic review, there was sufficient evidence to support skin-to-skin contact as a pain relieving intervention in preterm infants but not full-term neonates (Pillai Riddell et al., 2011). At present, the optimal exposure time for skin-to-skin contact prior to needle procedures is unknown and an insufficient exposure time in full-term neonates may explain the inconsistent findings. Skin-to-skin contact is described further by Johnston and Campbell-Yeo (Chapter 58, this volume).

Non-nutritive sucking involves the placement of a pacifier in an infant's mouth to stimulate sucking. Sucking is postulated to release neurotransmitters that modify pain perception (Buscemi et al., 2008). Non-nutritive sucking has been shown to reduce pain responses in preterm infants, full-term neonates, and older infants (Pillai Riddell et al., 2011). Adults may be required to keep pacifiers in place. The combination of sweet solutions and non-nutritive sucking may improve the effectiveness of non-nutritive sucking (Buscemi et al., 2008; Stevens et al., 2010).

Facilitated tucking or swaddling involves containing the infant's limbs close to the infant's trunk in a flexed position. This physical intervention has been shown to reduce pain in preterm infants and neonates (Pillai Riddell et al., 2011). Care must be taken to avoid over-bundling which contributes to elevated body temperature (van Sleuwen et al., 2007).

Some aforementioned physical interventions require the presence of a parent. Involving parents supports their preferences to be included in their infant's care and promotes parent–infant bonding (Franck et al., 2005; Gale et al., 2004), however, this may not always be possible.

## Upright positioning and holding

Upright position and parent holding are regarded as optimal ways to position children during needle procedures (Sparks et al., 2007; Taddio et al., 2009a). It is hypothesized that individuals feel less fear when positioned upright than when positioned supine (Lacey et al., 2008) and that parental holding adds support and comfort (Stephens et al., 1999). There are limited data, however, in young infants and one systematic review found conflicting evidence for a benefit of holding (and/or rocking; Pillai Riddell et al., 2011). Despite this result, upright positioning has been recommended beginning as soon as infants can hold themselves up (3–5 months; Stephens et al., 1999).

Several variations in positioning and holding have been suggested: the most popular involves seating children on a parent's lap, with the child facing the parent. Alternatively, children can sit on the examination table, with the parent holding the child around the trunk. Care must be taken to avoid restraining children as this can increase movement and distress (Stephens et al., 1999).

Upright positioning and parent holding is a simple, cost-free pain relieving intervention that can be employed in any clinical setting, provided that clinicians are comfortable with it. Some clinicians may be hesitant about this technique (Lacey et al., 2008; Sparks et al., 2007), due to perceptions that it is unsafe (i.e. children's extremities are insufficiently immobilized) and that it increases workload (i.e. requiring additional time or personnel). In addition, clinicians may have to modify their procedure technique to accommodate the child's position—this may cause some to feel insecure in their ability to carry out needle procedures successfully (Sparks et al., 2007). Methods to improve clinician experience and acceptability of this intervention are needed.

## Tactile stimulation

Tactile stimulation is a physical intervention that involves touching the skin near the procedure site. It may be delivered using a variety of techniques including rhythmic rubbing, manual pressure, pressure devices (e.g. ShotBlocker™), and vibration devices (e.g. Buzzy™). Most of the studies evaluating this intervention have utilized either rubbing or manual pressure delivered by the operator performing the procedure—both techniques are ideally suited for use in any clinically setting as they do not require any equipment, advanced preparation, or additional cost (Taddio et al., 2009a). The proposed mechanism of action is hypothesized to involve the 'gate control theory' of pain, whereby nociceptive signal transmission to the brain is reduced by simultaneous competitive transmission of touch sensation. The end result is a lower pain signal reaching the brain.

Tactile stimulation is currently not recommended for use in children less than 4 years of age due to lack of data supporting its effectiveness. Limited research in the infant population (Beaver, 1987; Hogan et al., 2013; Jain et al., 2006) does not demonstrate a clear benefit. One possible explanation for the negative result observed in one trial (Hogan et al., 2013) is that tactile stimulation was delivered by a parent instead of the health care provider. It is possible that the intervention was not delivered appropriately or that it interfered with the parent's ability to soothe infants. Additional investigation of the effectiveness of clinician-led tactile stimulation is recommended in this population.

## Cold

### Skin refrigerants/vapocoolants

A variety of volatile chemicals are associated with an evaporation-induced cooling sensation after application to the skin. Based on the hypothesis that cooling reduces pain sensation in cutaneous sensory neurons, these agents have been investigated as potential analgesics for needle procedures (Zempsky, 2008). At present, there are two marketed preparations: Ethyl Chloride® and Pain Ease®. They are sprayed on the site continuously until blanching of the skin is observed (and for up to 10 sec). The cooling effect is short-lived, necessitating needle insertion within 1 min, or re-application. Some individuals experience discomfort with application of these cold solutions; otherwise side effects are limited with appropriate use.

Numerous studies conducted over the past two decades have not demonstrated a consistent analgesic effect of vapocoolants, irrespective of age of the individual (child or adult) or procedure (venous access or injection) (Hogan et al., 2011a). Possible reasons for inconsistent results include: increased or reduced pain perception arising from the cooling sensation, varied administration methods, or mild (equivocal) effects (Shah et al., 2009; Zempsky, 2008). Vapocoolant sprays are therefore not recommended for widespread use.

### Ice

Based on the same mechanism of action as vapocoolant sprays, local cooling of the skin can be achieved via application of ice. Similar to studies of vapocoolant sprays, studies with ice do not demonstrate a consistent pattern of effectiveness (Movahedi et al., 2006; Taddio et al., 2009a). Hence, ice cannot be recommended as an analgesic for needle procedures.

### Combining the 4 Ps of pain management for needle pain

Needle pain is an iatrogenic harm; hence, the goal of pain management is to prevent it (Chorney et al., 2010). No single pain-relieving intervention reliably achieves analgesia, thus interventions should be combined to improve effectiveness. Pain treatments that are consistently applied for all needle procedures experienced commencing from birth ensure the greatest likelihood that procedures are minimally painful, if not pain-free, and that the negative sequelae of unmitigated pain are averted. When children are sufficiently mature and/or have developed coping strategies and preferences, pain management can be tailored to their preferences (Cheng et al., 2003; Kortessluoma et al., 2008).

Pain and anxiety might not be completely eliminated by use of pain-relieving interventions. Children may still be anxious because of negative previous experiences, unfamiliar individuals and/or settings, or other reasons. These circumstances in no way negate the use of pain-relieving interventions; instead, they call for additional interventions.

## Conclusion

Attending to pain from needle procedures undertaken in children supports children's health because it: (1) reduces acute suffering, which improves the experience of children undergoing needle procedures, their caregivers, and operators, and (2) reduces long-term harms, including non-compliance with future health care interventions as a result of minimizing the development of needle fears. Numerous evidence-based and feasible

interventions are available, however, at present, they are underutilized. Knowledge translation initiatives that target the family, health providers, and institutions are recommended to improve current practices (Zhu et al., 2012; Chan et al., 2013; Schechter et al., 2010) (described in detail by Yamada and Hutchinson, Chapter 61, this volume).

## CHAPTER 20

# Procedural sedation

Joseph P. Cravero

### Summary

Paediatric patients undergoing procedures often require sedation to provide the appropriate combination of anxiolysis, analgesia, and motionlessness. Due to the behavioural and developmental issues involved with this population, children actually require sedation to accomplish procedures much more often than adults. Paediatric sedation is a dynamic area of practice. Requests for this care continue to rise. The variety of providers involved in this care has also increased significantly. This chapter reviews the basic concepts involved in sedation delivery and then addresses the various considerations involved in sedation cases from the point of view of patient factors, procedure factors, and provider factors. Various drugs available for sedation are also reviewed with comments on appropriate strategies for a variety of common diagnostic and therapeutic procedures.

### Introduction

Providing pain control for children requires recognition of the distinct nature of this population when compared to adults. Emotional and behavioural issues change with every developmental stage. Even if pain can be controlled, the presence of strangers and medical equipment will upset many children. The result can be unwanted physical and/or psychological trauma to the child and difficulty in accomplishing the procedure for the health care provider. As a result, sedation is sometimes required (in addition to analgesia) in order to provide optimal care.

Over the last 30 years the delivery of sedation for children has changed considerably. Procedural sedation was, and in many places still is, disseminated among a large group of providers with little organization or strategic planning and with wide variation in approach. The last 10 years has seen the formation of paediatric sedation services across North America and Europe staffed by a variety of specialists including anaesthesiologists, emergency medicine providers, intensivists, and hospital-based paediatricians (Cravero, 2009; Cravero et al., 2006, 2009; Rodrigo, 1991; Rodrigo et al., 1992; Weinbroum et al., 2001). These highly organized services have proven to be efficient, safe, and have decreased variation, as tracked by the Pediatric Sedation Research Consortium (Cravero et al., 2006). Training in sedation has become a fundamental component of paediatric emergency medicine and intensive care fellowships in the US, Europe, and Australia (Ilkhanipour et al., 1994; Mintegi et al., 2008). With these changes in care and training, the level of expectations for the delivery of safe, efficient, and highly effective procedural sedation has been raised significantly.

It is imperative that professionals who provide sedation clearly understand the concepts that are the keys to sedation practice including the nature of sedation depth, sedation monitoring, pharmacodynamics/pharmacokinetics of the sedative agents, core competencies for sedation management, and issues involving recovery of patients after sedation. It is only with a clear understanding of these concepts that the goal of safely eliminating pain and anxiety from the experience of hospital procedures and tests can be realized for children.

### Background

#### Levels of sedation

Professional organizations have defined sedation in different ways. The American Academy of Pediatrics (AAP) and the American Academy of Pediatric Dentistry (AAPD) (Cote and Wilson, 2006), the American Society of Anesthesiologists (ASA; ASA Task Force on Sedation and Analgesia by Non-Anesthesiologists, 2002), and The Joint Commission (TJC; <<http://www.TheJointCommission.com>>) as well as the National Institute for Health and Clinical Excellence (NICE, 2010) in the UK have used the concept of levels of sedation ranging from minimally impaired consciousness to complete unconsciousness or general anaesthesia. On the other hand, the American College of Emergency Physicians prefers to refer to all sedation that is provided with the intent of accomplishing a test or procedure as 'procedural sedation' (Godwin, 2005) without emphasis on various depths of sedation.

Any provider who delivers sedation should recognize that different depths of sedation are possible and that risk for respiratory depression and cardiovascular changes are related to depth of sedation. Furthermore, a drug does not determine the depth of sedation that results from its administration. Any sedative drug, given a large enough dose, will produce complete unconsciousness and potentially dangerous outcomes (Cote et al., 2000b). The provider of sedation should be able to manage or rescue a patient from any level of sedation achieved.

The current levels of sedation defined by the AAP/AAPD, ASA, and NICE guidelines for management of patients during sedation include the following (Cote and Wilson, 2006):

#### Minimal sedation

A medically controlled state of depressed consciousness (formerly referred to as conscious sedation) which allows protective reflexes to be maintained; retains the patient's ability to maintain a patent airway

independently and continuously; and permits appropriate response by the patient to physical stimulation or verbal commands such as 'open your eyes'. Although cognitive function and coordination may be impaired, ventilatory and cardiovascular functions are unaffected.

### Moderate sedation/analgesia

A drug-induced depression of consciousness during which patients respond purposefully to verbal commands, either alone or accompanied by light tactile stimulation. No interventions are required to maintain a patent airway and spontaneous ventilation is adequate. Cardiovascular function is usually maintained.

### Deep sedation

A medically controlled state of depressed consciousness or unconsciousness from which the patient is not easily aroused. It may be accompanied by a partial or complete loss of protective reflexes, and includes the inability to maintain a patent airway independently and respond purposefully to physical stimulation or verbal command. Patients may require assistance in maintaining a patent airway and spontaneous ventilation may be inadequate. Cardiovascular function is usually maintained.

### General anaesthesia

General anaesthesia is a drug-induced loss of consciousness during which patients cannot be aroused, even by painful stimulation. The ability to independently maintain ventilatory function is often impaired. Patients often require assistance in maintaining a patent airway and positive pressure ventilation may be required because of depressed spontaneous ventilation or drug-induced depression of neuromuscular function. Cardiovascular function may be impaired.

The levels of sedation are *not* intended for use as a constant monitor of patient state. It is not practical to constantly stimulate patients to test their depth of sedation. Rather, these levels can be used to observe patient behaviour and codify patient risk based on response to stimuli that might occur during the course of a procedure.

### Sedation depth monitoring

There are several monitors of depth of anaesthesia/sedation. The most commonly employed monitor is the Bispectral Index (BIS) monitor. This instrument uses a proprietary algorithm to process selected electroencephalographic (EEG) output into a number (from 0 to 100) that reflects the depth of sedation. While some investigators have validated its use during sedation of children (McDermott et al., 2003), it has not been found to be particularly useful during procedural sedation. Studies have found the BIS reading does not match well with clinical assessment of the depth of sedation, particularly when ketamine or combinations of sedation medications are utilized (Shields et al., 2005).

Several sedation monitoring scales are available for use during sedation activity. Unfortunately most have been designed for sedation depth monitoring in the intensive care unit (ICU) environment and, in order to test the depth of sedation, most of them require stimulation and documentation of response. The University of Michigan Sedation Score (UMSS) (Box 20.1) has been widely used and has undergone testing for validity. It is simple to use (repeatedly) during the course of a sedation activity (Malviya et al., 2002; Mason et al., 2004). Other sedation scores include the

#### Box 20.1 University of Michigan Sedation Score

Level state:

0 = Awake/alert.

1 = Minimally sedated: tired/sleepy, appropriate response to verbal conversation and/or sounds.

2 = Moderately sedated: somnolent/sleeping, easily aroused with light tactile stimulation.

3 = Deeply sedated: deep sleep, arousable only with significant physical stimulation.

4 = Unarousable

Observer's Assessment of Alertness/Sedation Scale (Chernik et al., 1990), Comfort Score, Modified Ramsey Sedation Score, and the Children's Hospital of Wisconsin Sedation Scale (Ista et al., 2005). All of these scales measure levels of consciousness and agitation while the Comfort Scale and the Modified Ramsey Scale also include an assessment of pain and ventilation. While the scales have been compared to one another in various studies over the years, no specific scale has been shown to improve patient outcome or sedation provision over the others (De Jonghe et al., 2000).

### Planning for sedation

There are many factors that impact the manner in which sedation should be provided. Every child should undergo a pre-sedation health assessment. This assessment should include age, weight, past medical history, vital signs, physical examination, and ASA status (Cote and Wilson, 2006).

While the pre-sedation examination of the patient is undoubtedly important in planning sedation for a procedure or test, this assessment is only one of a larger number of factors that must be considered including those related to the patient, the procedure, and the provider.

### Factors relating to the patient

#### Past experience

As part of a detailed sedation history prior to the procedure the previous experiences of the patient should be elicited. For example, a patient who became combative with a dose of oral midazolam would not be well served by repeating that drug for another procedure. The sedation provider should also consider the anxiety level of the patient and family. The severely anxious patient will often need significantly more pharmacological sedation where a relaxed patient may only need support or distraction (Mintegi et al., 2008). Child life or play therapists can play an integral role in determining the optimal strategy for managing each patient's emotional and psychological needs (Brewer et al., 2006; Stevenson et al., 2005).

#### Allergies and adverse reactions

It is imperative that a drug allergy and adverse reaction history be elicited prior to providing sedation. Reports of an allergy to a given

medication should be followed up with a history of the nature of the reaction. Drugs that were associated with truly allergic symptomatology (such as rash or wheezing) should be avoided. Families commonly interpret nausea or odd behaviour after sedation as an allergy. In fact these issues are often commonly known reactions to a medication or procedure. Nausea and vomiting are always possible after sedation—particularly with medications such as ketamine (Langston et al., 2008). Anticipatory treatment with 5HT3 inhibitors or steroids may decrease nausea and vomiting effects (Gan et al., 2007). Approximately 2% of patients will have paradoxical reactions to sedative medications such as midazolam or chloral hydrate (Sakurai et al. 2010). In these cases crying and combative behaviour is elicited shortly after administration rather than the desired sedation. Observational studies suggest the use of the benzodiazepine reversal agent romazicon can be useful in truncating the behaviour (Rodrigo, 1991; Weinbroum et al., 2001). Emergence agitation has been described during the recovery phase after sedation (Karaaslan et al., 2006). In these cases, patients may be delirious and combative for a period of 10 to 30 min (rarely longer) on awakening from sedation.

**NPO status and assessment of aspiration risk**

The ASA and AAP (ASA Task Force on Preoperative Fasting, 1999, Cote and Wilson, 2006) guidelines have historically taken the approach that anyone receiving moderate sedation or deep sedation should be treated similarly to those receiving anaesthesia regarding the timing of oral intake to prevent aspiration (Table 20.1) The authors argue that since sedation depth is variable it is possible that patients will enter a state where they will have impaired airway protective reflexes even when moderated sedation is targeted.

In the UK, NICE guidelines recommend nothing by mouth (NPO) intervals of 2 h for clear liquids, 4 h for breast milk, and 6 h for solids (NICE, 2010) Fasting is not recommended for individuals who will receive minimal sedation or moderate sedation where verbal contact will be monitored and maintained throughout.

Recently, two retrospective reviews have questioned the application of these guidelines to the field of paediatric sedation. These studies reviewed the charts of over 2400 emergency department paediatric sedation encounters and found no relationship between NPO duration prior to sedation and adverse outcomes (Agrawal et al., 2003; Roback et al., 2004). In light of this data, the American College of Emergency Physicians has developed its own set of fasting guidelines that differs significantly from the ASA (Green et al., 2007).

In addition to the history of oral intake, the ASA Practice Guidelines for Perioperative Fasting recommend that a history of

gastro-oesophageal reflux disease should be considered a risk factor for pulmonary aspiration during sedation or anaesthesia (ASA Committee on Standards and Practice Parameters, 2011).

**General health**

The general health status for each patient who presents for sedation should be assessed. A general physical examination with focus on the airway, cardiovascular, and respiratory systems is critical.

The ASA status classification system categorizes individuals based on a general health (ASA Committee on Standards and Practice Parameters, 2011) (Table 20.2). Rather than focus on any specific disease entity, the ASA status is intended to group patients together based on their health status in order to better assess the risk of anaesthesia or sedation. Several studies have documented that the risk for any complication during sedation (desaturation episodes, airway obstruction, hypotension) rises by four- to fivefold with increasing ASA status (Cravero et al., 2009; Krauss and Green, 2008).

**Airway issues**

As part of the pre-sedation evaluation, specific abnormalities of the airway should be noted. These issues can be divided into two general categories: (1) the difficult functional airway, and (2) the difficult anatomical airway (Sims and von Ungern-Sternberg, 2012).

The difficult functional airway refers to those patients who are expected to have difficulty exchanging air through their natural airway when sedated. Children in this category would include those with severe sleep apnoea, obesity, recurrent croup, markedly enlarged tonsils, or those with congenital anomalies that make sleeping supine difficult or impossible (Donnelly et al., 2000). When children in this category are sedated to the point of unconsciousness, airway obstruction would be much more common than in healthy children (Adewale, 2009).

**Table 20.2** Outline of the ASA physical status criteria

ASA class	Description
1	A normal, healthy patient, without organic, physiological, or psychiatric disturbance
2	A patient with controlled medical conditions without significant systemic effects
3	A patient having medical conditions with significant systemic effects intermittently associated with significant functional compromise
4	A patient with a medical condition that is poorly controlled, associated with significant dysfunction and is a potential threat to life
5	A patient with a critical medical condition that is associated with little chance of survival with or without the surgical procedure
6	A patient who is brain dead and undergoing anaesthesia care for the purposes of organ donation
E	This modifier is added to any of the above classes to signify a procedure that is being performed as an emergency and may be associated with a suboptimal opportunity for risk modification

**Table 20.1** ASA fasting guidelines for sedation or anaesthesia

Food	Hours of fasting required
Clear liquids	2
Breast milk	4
Formula or light meal (no fat)	6
Full meal	8

The difficult anatomical airway subgroup includes patients in whom the visualization of the airway with a standard direct laryngoscopy is expected to be difficult. The sedation provider must note this issue even if intubation is not planned. Since definitive airway management with an endotracheal tube is the ultimate rescue manoeuvre for children who are severely compromised during sedation, it is critical to anticipate if this is going to be a difficult intervention. A small or malformed mandible or a large tongue is often associated with difficult visualization of the glottis (Sims and von Ungern-Sternberg, 2012). Teeth that are protruding or particularly loose should be noted as they may hinder airway visualization or be knocked free during manipulation. Furthermore any patient who has limited neck mobility (such as trauma or burn patients) may be difficult to position in a manner that makes laryngoscopy possible. Finally any syndrome that results in an unusual facial appearance should be carefully noted as they may also be associated with an airway that is difficult to visualize (Candido et al., 2000; Sarvet and Brewer, 2011).

### Developmental issues

The neurodevelopmental status of the child should be noted prior to planning sedation. Requirements for sedation will change greatly for any child who is severely delayed and/or autistic (Pasternak, 2002). Furthermore induction of sedation can be very difficult in large patients who cannot, or will not, cooperate with starting an intravenous (IV) line or taking oral medications (Rodrigo, 1995). Input from the family, primary care givers, and/or Child Life Specialists can be critical in determining the best strategies for accomplishing sedation and the amount of intervention that will be required for a given procedure (Mintegi et al., 2008).

### Cardiac and respiratory systems

As already mentioned, the cardiac and pulmonary systems must be assessed prior to beginning sedation. In particular, patients with pulmonary hypertension may have significantly adverse reactions to hypoventilation and increased carbon dioxide ( $\text{CO}_2$ ), or hypoxia, which can easily occur with sedation (Carmosino et al., 2007). In children with complex anatomical defects, the degree of left-to-right or right-to-left shunting may be changed by pulmonary or systemic vasodilation which can be a side effect of sedation medications. Patients with complex congenital heart disease should be sedated by practitioners who understand their physiology completely and also understand the physiological implications of sedation.

### Respiratory illness

Although little data exists concerning the risk of sedation for patients with asthma, data from anaesthesia literature indicate that an asthmatic should be in the patient's best possible condition prior to beginning the procedure (Dones et al., 2012). Management should include administration of all currently prescribed inhalers prior to the sedation and assuring that the child is not actively wheezing at the time of sedation (Doherty et al., 2005).

There is little data to indicate the impact of an upper respiratory tract infection (URTI) on the success or safety of procedural sedation. URIs are extremely common during the winter months with as many as 20% to 30% of the paediatric population having symptoms of an upper respiratory infection (Zaman et al., 1997). While it is simply not practical to cancel all procedures in this patient group, several studies have found an increase in airway and respiratory

complications when they have surgery while experiencing a URTI (Homer et al., 2007). These problems include oxygen desaturation, increased secretions, laryngospasm, and coughing. The risk period exists not only during the time the child has the URI, but for approximately 2 weeks after the child is symptomatically improved (von Ungern-Sternberg et al., 2010). Fortunately, the frequency of severe complications (such as cardiac arrest, unexpected admissions, neurological injury, or death) have not been determined to be increased for this population (Tait and Malviya, 2005). It is prudent for sedation providers to consider the presence of a URTI when evaluating a child for sedation. If the procedure is going to be extended and/or if absolute movement control is required, it may be wise to reschedule an elective intervention even if symptoms are limited to the upper airway. If sedation is provided for those with a limited URTI the post-procedural observation may need to be extended (Homer et al., 2007). Elective sedation should be postponed in children who have a fever, or those with a significant cough and sputum production, rales, or wheezing.

### Factors relating to the procedure

When choosing a sedation medication or technique, the provider should consider the time that the procedure will require to be accomplished. For drugs that are given as a single dose orally or nasally it is appropriate to match the duration of the procedure with the duration of the sedative. For short acting sedatives that are given as infusions—such as propofol, short or long duration procedures are equally easily accommodated. (Cravero et al., 2009; Wheeler et al., 2003)

An essential aspect of sedation that must be considered is the presence or absence of pain with any given procedure. Many of the sedatives that are commonly used for sedation—such as chloral hydrate, benzodiazepines, and even propofol—have no analgesic component (Jayabose et al., 2001; White and Romero, 2006). Options such as fentanyl, ketamine, and/or local anaesthesia should be considered to complement the effects of the purely sedative medications in these cases (Singh et al., 2010). It should be noted however, that the addition of opiates to other sedatives will significantly potentiate the probability of apnoea or airway obstruction (Taylor et al., 1986).

The provider must consider the position that the patient will be in during the procedure. Position can affect access to the airway during the procedure. Most children will maintain an open airway in the supine position when deeply sedated as long as the neck can be slightly extended and jaw lifted slightly forward (Shorten et al., 1995). If there is no access to the head, or if the head must be flexed during a procedure or a scan, obstruction of the airway will be much more likely (Isono et al., 2004). Care should be taken to avoid deep sedation unless the provider is ready to provide positive pressure ventilation. Airway resistance is actually decreased when a child is placed in the lateral decubitus or prone position (Violet and Nau, 2009). While definitive management of the airway may be more complicated in these positions, spontaneous ventilation is often improved when compared to supine position if all other factors are unchanged.

Sedation should be considered for procedures that are particularly emotionally stressful even if not necessarily painful, but where a brief period of unconsciousness will allow the patient to avoid an emotionally harmful experience. Often these procedures involve

invasion or examination of the genitalia (such as sexual abuse evaluations) or voiding cystourethrograms (Harari and Netzer, 1994).

### Factors related to the sedation provider

When moderate or deep sedation is induced at least one person, in addition to the clinician performing the procedure, should be present to help care for the patient (Cote and Wilson, 2006). This person's responsibility is to monitor parameters such as pulse oximetry, heart rate, ventilation, and blood pressure and to assist in any supportive or resuscitation measures, as required. It is strongly encouraged that this individual at a minimum be trained in paediatric basic life support. Current knowledge of the emergency cart access/inventory as well as knowledge of how to activate back-up systems is critical (ASA Task Force on Sedation and Analgesia by Non-Anesthesiologists, 2002; Cote et al., 2006).

Sedation systems and sedation providers must recognize that the skill and training of providers of sedation varies greatly. The provider should be readily able to rescue that patient from the potential side effects of unexpected deepening sedation—which includes loss of airway integrity and spontaneous ventilation. Those who provide deep sedation for children should be able to rescue a child from the possible effects of general anaesthesia including definitive management of the airway and cardiovascular depression.

Studies of sedation related critical events have shown that severe adverse outcomes are most common in venues where a good backup or rescue system is not available (Cote et al., 2000a, 2000b, 2000c). Furthermore, sedation rescue has been shown to vary greatly between sedation providers and sedation settings (Blike et al., 2001). Given this evidence, it is logical that a protocol for accessing the backup help for sedation critical events (hospital resuscitation team or emergency medical systems) should be clearly laid out and tested.

### Equipment needs for sedation

The following equipment is necessary for sedation. A bag and mask for positive pressure ventilation, masks of appropriate size for any patient, a second backup source of oxygen, a variety of sizes of oral and nasal suction equipment.

Vital signs, including oxygen saturation via pulse oximetry and heart rate, should be documented at least every 5 min in a time-based record. While the pulse oximeter measures oxygenation it does not directly measure ventilation. Depending on the amount of oxygen that the patient is breathing, there can be significant lag time between the onset of apnoea and oxygen desaturation (Langhan et al., 2012; Lightdale et al., 2006). In addition, a patient may experience significant hypoventilation but have acceptable oxygen saturation if receiving high-flow oxygen.

There are several methods for monitoring ventilation. The most basic is direct observation of the patient—noting coordinated chest wall/abdominal wall motion. When observation is not possible, other methods such as a precordial stethoscope or capnography should be used.

Capnography measures and displays CO<sub>2</sub> levels sampled from the breathing interface of the patient. For patients who are not intubated, a side stream detection technique is most often employed in which a small amount of gas (50–100 cc/min) is continuously sampled from the nasal cannula or inside of the mask on the patient. Apnoea is detected as soon as it occurs since it would result in an immediate loss of the expired CO<sub>2</sub> waveform (Figure 20.1).

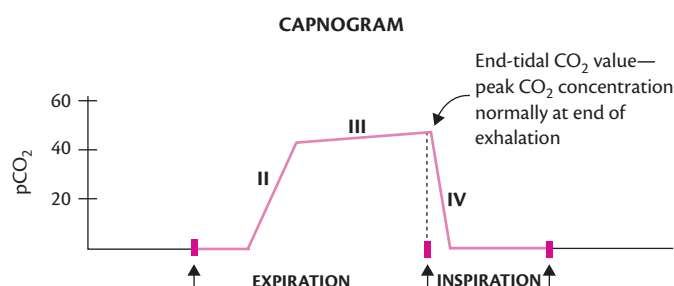

Figure 20.1 Key aspects of the capnogram.

Components of the normal capnogram:

- I—(near zero baseline). Exhalation of CO<sub>2</sub> free gas contained in dead space.
- II—(rapid sharp rise). Exhalation of mixed dead space and alveolar gas.
- III—(alveolar plateau). Exhalation of mostly alveolar gas.
- IV—(rapid sharp downstroke). Inhalation.

## Sedation drugs

### Hypnotic medications (sedatives)

#### Chloral hydrate

Chloral hydrate is a halogenated hydrocarbon that has been used as a sedative for 90 years. The common doses used vary between 20 to 75 mg/kg orally. Most practitioners limit the dose to 100 mg/kg or a total dose of 2 g (Greenberg et al., 1991). The pharmacokinetics of chloral hydrate are somewhat prolonged. The peak effect may not be seen for 60 min and the plasma half-life is 4 to 9 h. The drug can result in prolonged sedation, particularly in infants, with peak effect occurring well after the intended time of desired sedation (Cote, 1994; Malviya et al., 2000). On the other hand, the drug rarely results in respiratory depression (Sanborn et al., 2005). The potential for respiratory compromise does exist however, and is most marked when combined with opioids or other sedatives. Deaths have been reported with doses of chloral hydrate in the recommended range.

This drug is of limited use for painful procedures since it lacks analgesic effect. In addition, the prolonged onset time and duration do not match well with many paediatric procedures. Emergence can be marked by behavioural disturbances and agitation. It may still have a niche for use during radiology procedures such as magnetic resonance imaging (MRI) scans or for electroencephalograms. The drug is most effective in infants and toddlers.

In the spring of 2012 the only manufacturer of chloral hydrate in the US ceased production. It is still available in most areas outside of the US including Canada, Europe, and Asia (FDA, 2012).

#### Midazolam

Midazolam is a short-acting benzodiazepine that is widely used for anxiolysis and sedation. It has become particularly popular because of its short duration, predictable onset, and lack of active metabolites. Prominent effects include skeletal muscle relaxation, amnesia, and anxiolysis (Kain et al., 2000).

Although originally formulated for IV use, the same medication used orally has proven very successful in producing minimal to moderate sedation and amnesia (Malinovsky et al., 1995;

McMillan et al., 1992). The recommended oral dose is 0.5 to 0.75 mg/kg, with onset of sedation in approximately 15 min. Offset occurs approximately 30 min after the peak effect is noted. Oral midazolam is excellent for minor invasive procedures such as IV catheter placement or minor laceration repair when combined with local anaesthesia.

Midazolam may be given by the intranasal route at doses of 0.2 to 0.4 mg/kg (Harcke et al., 1995). Onset time is intermediate between the oral and IV routes of administration (10–15 min). The effectiveness of this route of administration is well established as a premedication for anaesthesia and sedation for minor procedures but its use is limited by significant discomfort on administration. Recent studies have noted that discomfort may be minimized through the use of a mucosal atomizer device for administration and pretreatment with lidocaine on the nasal mucosa (Chiaretti et al., 2011).

IV midazolam is titrated to effect with fractionated doses of 0.05 to 0.10 mg/kg that may be repeated at intervals of 3 to 4 min to a total dose of 0.5 to 0.7 mg/kg. IV midazolam reaches peak effect in 2 to 3 min. Slow IV administration is recommended with close observation for respiratory depression. When combined with IV opioids for painful procedures, midazolam has much more potent sedative and respiratory depressant effects when compared to its use as a single agent.

Respiratory depression is rare with administration of midazolam in recommended doses regardless of the route of administration. Patients are generally relaxed and drowsy after administration. One of the most desirable side effects is the anterograde amnesia. The extent of this effect will vary with the age of the patient and the dose employed.

Certain underlying conditions or medications may prolong the effects of midazolam. Heparin decreases protein binding and increases the free fraction. Hepatic metabolism is inhibited by cimetidine which prolongs the elimination half-life. Patients in renal failure may have three times the free fraction of the drug secondary to decreased protein binding.

### Pentobarbital

Pentobarbital has potent sedative hypnotic properties, but it has no analgesic properties. Onset of action after IV administration is rapid, resulting in moderate–deep sedation within 3 to 5 min. The effective dose ranges from 3 to 6 mg/kg for over 98% of patients (Greenberg et al., 2000). Highest success rates are reported when the drug is used for patients under 12 years old and under 50 kg. The incidence of respiratory depression is less than 1% when pentobarbital is used as a sole agent at the recommended dosages (Sanborn et al., 2005). Failure to achieve sedation rates have been reported in 1.2% of patients when confined to this population. Paradoxical reactions leading to agitation occur in approximately 1% of patients. Pentobarbital is used in 14% of all sedations from an international collaboration of over 30 institutions (Cravero et al., 2006). Given the collected data on this drug reviewed above, pentobarbital is a reasonable choice for patients undergoing painless radiological procedures.

### Intravenous propofol

Propofol is a 2, 6-diisopropylphenol compound that has potent sedative and hypnotic properties. The highly lipophilic nature of the drug requires that it be delivered in a lipid emulsion. It can only be delivered by the IV route. Onset of action is extremely rapid

and induction of deep sedation/anaesthesia may be achieved with 2 to 3 mg/kg in 95% of patients within 60 to 90 sec. Sleep may be induced with as little as 1.5 mg/kg and maintenance of sedation is usually accomplished through the use of an IV infusion at 50 to 200 mcg/kg/minute. Recovery from the drug is faster than with any other IV sedative (2–3 min redistribution time) and the incidence of prolonged sedation or vomiting is extremely low. A dose-related decrease in blood pressure is noted that is similar to that found with other anaesthetics (Hertzog et al., 1999).

To reduce pain associated with injection a small dose of lidocaine (1 mg/kg) can be given through the IV catheter prior to administration or propofol can be given through a fast-flowing IV line into a large vein.

Some hospitals limit propofol use to anaesthesia personnel however studies have described the role of this drug in the ICU and emergency department (Barbi et al., 2003; Bassett et al., 2003; Guenther et al., 2003). A recent report found excellent effectiveness with a low rate of adverse events among sedation services using propofol for procedural sedation in children (Cravero et al., 2009). Airway interventions (intubation, bag-mask ventilation, or oral/nasal airway insertions) were required in approximately one out of 65 sedated patients in this cohort. The authors of these and other studies emphasize that safe use of propofol for sedation requires proven competencies in airway management.

### Intravenous dexmedetomidine

Dexmedetomidine (DEX) has become increasingly popular as a sedative for radiological tests and procedures. This drug produces a sedated state with a small component of analgesia and little decrease in respiratory drive. DEX is an  $\alpha_2$  agonist with a short half-life that is generally given in a bolus (0.5–1 mcg/kg over 10 min) followed by constant infusion (0.5–2 mcg/kg/h; Tobias and Berkenbosch, 2002; Tobias et al., 2003). In order to maximize effectiveness, doses two to three times this amount have been reported in patients aged 1 to 8 years (Mason et al., 2008b).

DEX has been reported for sedation of children on ventilators in the paediatric intensive care unit and as a sedative for procedures (Berkenbosch et al., 2005; Tobias and Berkenbosch, 2002). In one series of over 700 patients given 2 to 3 mcg/kg as a loading dose followed by infusions of 1.5 to 2.0 mcg/kg/h, no respiratory adverse events were reported (Mason et al., 2008c). Caution is warranted as hypertension, hypotension, and bradycardia have been reported side effects with DEX (Mason et al., 2008a, 2008b).

## Analgesic medications

### Fentanyl

Fentanyl is a synthetic opioid which is 100 times more potent than morphine. It has a very high degree of fat solubility that allows for very rapid penetration of the blood–brain barrier (Cote, 1994). The sedation effects are relatively brief as the offset of the drug is dependent on redistribution rather than elimination.

The IV dose recommendation for fentanyl is 0.5 to 1 mcg/kg/dose for procedures associated with significant pain such as lumbar punctures, bone marrow biopsies, bronchoscopies, minor surgical procedures, and central venous catheter placement (Chiaretti et al., 2011). Fentanyl as a sole agent offers excellent pain relief with mild sedation at these doses. Maximal effect occurs within 5 min when administered intravenously. Opioid effects last for 30

to 40 min. More often fentanyl is combined with sedatives to provide an analgesic component to sedation. There are reports of its use in combination with benzodiazepines or propofol for endoscopy (Langhan et al., 2012), haematology/oncology procedures (Langhan, 2011; Langhan et al., 2012), and invasive line placement (Chiaretti et al., 2011).

Chest wall rigidity may occur with IV fentanyl dosing and is particularly problematic when the drug is rapidly administered (Scamman, 1983). Respiratory depression is markedly increased when the drug is combined with midazolam or other sedative (Kennedy et al., 1998). Naloxone should be readily available when Fentanyl is administered.

### Ketamine

Ketamine is a phencyclidine derivative. It blocks N-methyl-D-aspartate receptors to produce intense analgesic and sedative qualities. Its use has been described for over 40 years as a sedative for painful procedures in children (Green et al., 1990, 2001). A functional dissociation is created between the cortical and limbic systems of the brain. Spontaneous respirations and airway reflexes are maintained. Patients may exhibit random tonic movements of the extremities that make this drug inappropriate for procedures where the patient must lie perfectly still (i.e. computed tomography and MRI scans). Ketamine generally causes an increase in heart rate, blood pressure, cardiac output, and intracranial pressure. Oral secretions may be mildly increased although a recent meta-analysis of ketamine data suggests an increase in complications when combined with anticholinergics (Green et al., 2009). Ketamine has bronchodilator qualities making it ideal for use in children with issues relating to bronchospasm.

Ketamine can be given orally at a dose of 5 to 6 mg/kg. Onset of sedation occurs in 15 to 30 min and effects may be prolonged with this route—lasting 3 to 4 h (Rowland et al., 1995; Srinivasan et al., 2012). Intramuscular (IM) ketamine reaches peak blood levels and clinical effect in 5 min after a 3 to 5 mg/kg IM injection. Recovery from dissociation occurs within 15 to 30 min with coherence and purposeful neuromuscular activity returning in 30 to 120 min (Sanderson, 1997). There are two formulations for ketamine—10 mg/ml and 100 mg/ml. The more concentrated formulation of ketamine is preferred for IM administration. IM ketamine has been widely reported in the paediatric emergency medicine literature for sedation during painful procedures such as facial laceration repair, fracture reduction, abscess incision and drainage, and foreign body removal (Bloomfield et al., 1993; Sanderson, 1997). Ketamine can also be given intramuscularly to uncooperative patients in whom IV or oral administration of ketamine or other sedatives is not possible (Pershad et al., 2007).

Ketamine may be given in small IV doses of 0.5 to 1 mg/kg to produce rapid and profound sedation with analgesia. Peak concentrations occur within 1 min and allow almost immediate induction of clinical effects and lasts 15 min if no additional doses are given (Clements and Nimmo, 1981). Painful procedures are tolerated well following administration of ketamine because of its profound analgesic properties. IV ketamine is ideal for painful procedures such as burn debridement, foreign body removal, abscess incision, and orthopaedic procedures with a success rate over 98% (Baculard et al., 2007; Kienstra et al., 2004).

Adverse events under ketamine sedation are similar regardless of the route of administration. Nausea and vomiting has been

described in 5% to 13% of children receiving ketamine (Bloomfield et al., 1993) while agitation on emergence is noted in 12% to 22% (Kienstra et al., 2004). Respiratory drive is not inhibited by ketamine and airway reflexes are largely left intact. A pooled analysis of ketamine sedation in over 8000 patients found an airway adverse event rate of less than 4% with the majority of events consisting of oxygen desaturation responsive to minimal intervention (Green et al., 2009).

### Nitrous oxide

Nitrous oxide ( $N_2O$ ) was described for use as an analgesic/anaesthetic over 100 years ago. It is a colourless, odourless gas that has analgesic, anxiolytic, and weak sedative effects. The drug may be delivered alone at concentrations of 30% to 70% for moderately painful procedures (Zier et al., 2008) or in combination with a mild sedative at lower concentrations for similar effect (Litman et al., 1998a). Onset of sedation and analgesia occurs in minutes and is terminated rapidly when the gas is discontinued.  $N_2O$  has minimal cardiovascular and respiratory effects when *not* combined with a potent sedative or opioid. It appears to cause a synergistic increase in sedation when used with other sedative or analgesic medications. (Litman et al., 1998b)

Current systems for administering  $N_2O$  include continuous flow systems that deliver anywhere from 0% to 70%  $N_2O$  and older 'demand valve' systems that use a premixed 50% mixture of  $N_2O$  in oxygen. Demand valve systems require the patient to initiate negative pressure to open the inspiratory valve of the system (Farrell et al., 2008). This can be difficult for some toddlers and thus the continuous flow systems are preferable for the youngest patients. Scavenging systems should be available for  $N_2O$  at any location that it is being delivered (Rowland et al., 1995). Recent studies have shown excellent safety outcomes (no apnoea or airway interventions in over 5000 patient encounters) for 70%  $N_2O$  administered by continuous flow to paediatric patients (Farrell et al., 2008; Zier and Liu, 2011).

### Reversal agents

Reversal agents should be available when performing sedation with a benzodiazepine or opioid. Flumazenil can be used to reverse the effects of benzodiazepines and should be immediately available when using benzodiazepines for sedation. A dose of 0.01 mg/kg should be administered initially. Although rare, re-sedation may occur and additional doses of flumazenil may be required.

Naloxone (Narcan®) is an opioid antagonist and can be given intravenously, intramuscularly, or subcutaneously. The drug should be given in a slowly titrated manner when possible. The standard preparation contains 0.4 mg/cc of naloxone. The dose for children is 0.1 mg/kg for children under 20 kg. The dose for children over 20 kg is 2 mg (Table 20.3).

### Discharge

The criteria for discharge from a sedated procedure should include stable vital signs; pain under control; a return to the level of consciousness that is similar to the baseline for that patient; adequate head control and muscle strength to maintain a patent airway; nausea and/or vomiting should be controlled; and the patient should be adequately hydrated.

**Table 20.3** Sedation regimens

Propofol	50–200 mcg/kg/min IV	Non-painful procedures
Pentobarbital	3–6 mg/kg IV or PO	Radiology imaging
Midazolam	0.5–0.75 mg/kg PO 0.025–0.5 mg/kg IV 0.2 mg/kg intranasal	Anxiolysis, premedication, procedural sedation along with a topical anaesthetic or opioid
Chloral hydrate	50–100 mg/kg PO	Imaging, EEG, not commercially available in the US. Prolonged sedation
Dexmedetomidine	0.5–2.0 mcg/kg bolus (over 10 min) followed by 1–2 mcg/kg/h infusion.	For procedural sedation
Propofol with fentanyl	Fentanyl 1–2 mcg/kg IV with Propofol 5–10 mg/kg boluses	Painful procedures
Midazolam with fentanyl	Midazolam 0.020 mg/kg IV Fentanyl 1–2 mcg/kg IV	Painful procedures
Ketamine	3–4 mg/kg IM 1–2 mg/kg IV	Painful procedures

Even when these criteria are used children have been found to be discharged with residual sedation effects (Malviya et al., 2004). In particular, children who have received a large dose of long-acting sedation medications (such as chloral hydrate) are very prone to re-sedation after vigorous efforts are made to rouse them. These patients should not be discharged until they have demonstrated that they can maintain wakefulness for 15 min or more.

### Case example

**Presentation:** an 8-year-old, 35-kg girl with acute lymphoblastic leukaemia presents for a lumbar puncture with intrathecal chemotherapy administration.

**Management:** the child is held in mother's arms (as is her preference) while an IV infusion begun. She is given 0.5 mcg/kg of fentanyl followed by 1 mg/kg of propofol as a slow IV push. As she starts to become sleepy she is placed in a left lateral decubitus position with nasal cannula oxygen equipped with end-tidal CO<sub>2</sub> monitoring. A pulse oximeter and blood pressure cuff are also placed. After 3 min she is deeply sedated as evidenced by no response to voice and minimal movement when 2 mg of 2% lidocaine is infiltrated subcutaneously in the L3 to L4 interspace. She receives no further sedation and does not move during the lumbar puncture procedure. Heart rate is steady at 90 and her pulse oximeter remains at 98%. Breathing is partially obstructed and is easily improved with minimal jaw thrust—not required after about 2 min. She wakes up 9 min after procedure is completed and eats an ice lolly at that point.

**Comment:** this case is an example of a painful procedure where an analgesic (fentanyl) is used in conjunction with the sedative (propofol). The combination results in deep sedation which can (and does in this case) result in partial loss of airway tone requiring some airway manipulation. The sedation is very effective and results in movement control that would likely not be possible if analgesic were not added to the propofol. Of note, the providers allowed the child to choose how she would approach induction. This is particularly important for children such as this who will

undergo a large number of procedures and tend to focus on the process over time.

**Conclusions:** procedures result in fear and anxiety and may involve pain as well in children. Sedation is not always required, but may help eliminate unwanted long-term behavioural and psychological outcomes from invasive procedures. The need for pharmacological intervention should be determined by the developmental status, the level of anxiety, and context of the procedure. The formation of expert teams of providers is critical to optimal outcomes.

## CHAPTER 21

# Neuropathic pain in children

Suellen M. Walker

### Summary

Lesions or disease of the somatosensory nervous system can produce neuropathic pain (NP). Typical features include spontaneous or paroxysmal pain, often described as burning, shooting, like electric shocks, or pins and needles. NP does occur in childhood, but age at the time of injury may influence the risk of NP following traumatic nerve injuries. While conditions commonly associated with NP in adults may be less common in childhood (e.g. trigeminal neuralgia) other conditions (e.g. Fabry's disease and erythromelalgia), may present with pain in childhood and present a diagnostic challenge for paediatric practitioners.

### Introduction

Neuropathic pain (NP) has been defined as pain caused by a lesion or disease of the somatosensory nervous system (Jensen et al., 2011). Chronic pain is reported by up to 6% of children and adolescents (van Dijk et al., 2006), but the proportion with NP is not clear. However, children with neuropathic pain or complex regional pain syndrome (CRPS) comprise a significant proportion of cases referred to paediatric chronic pain clinics (Howard, 2011; Martin et al., 2010). Epidemiological studies suggest a prevalence of chronic pain with neuropathic features of 3.3% to 8.2% in the adult population (Haanpaa et al., 2011; Smith and Torrance, 2012); but conditions associated with NP in children differ from those commonly reported in adults (Borsook, 2012):

- ♦ Many conditions associated with NP in adults are rare or not associated with significant pain in children (e.g. Parkinson's disease, Alzheimer's disease, post-stroke pain).
- ♦ The incidence of post-herpetic neuralgia and trigeminal neuralgia is much lower in children (Hall et al., 2006).
- ♦ Painful diabetic neuropathy is a feature of more prolonged disease and is rarely reported before 14 years of age (Hall et al., 2006), but sensory changes have been detected in children prior to onset of pain (Blankenburg et al., 2012).
- ♦ Some NP conditions are increasingly recognized in children (e.g. CRPS, phantom limb pain, or NP following trauma or surgery; Walco et al., 2010).
- ♦ NP may be the presenting symptom during childhood of specific genetic conditions (e.g. Fabry's disease or erythromelalgia; Fischer and Waxman, 2010; Ramaswami, 2008).

- ♦ Children may have increased susceptibility to certain types of painful neurological injury (e.g. toxicity following mercury exposure; Celebi et al., 2008).

NP may be considered as a clinical entity in its own right with a common pattern of symptoms and signs, often with similar management irrespective of the underlying cause (Table 21.1). In later sections of this chapter, NP associated with specific conditions in children will be outlined. The classification of CRPS as a neuropathic pain condition is debated, but in this volume is included in Chapter 24 by Clinch. Pharmacological management of NP is often extrapolated from adult data (Attal et al., 2010; Dworkin et al., 2010; see Rastogi and Campbell, Chapter 48, this volume). Laboratory data regarding mechanisms and effects of nerve injury in early life are discussed by Vega-Avelaria and Beggs (Chapter 7, this volume).

### Assessment and diagnostic features

Current guidelines for the assessment and diagnosis of NP are designed for adults (Haanpaa et al., 2011), but are often extrapolated to older children or adolescents features include:

- ♦ Screening questionnaires to identify neuropathic pain include: LANSS, Leeds Assessment of Neuropathic Symptoms and Signs (Bennett, 2001); DN4, Douleur Neuropathique en 4 questions (Bouhassira et al., 2005); NPQ, Neuropathic Pain Questionnaire (Krause and Backonja, 2003); painDETECT (Freynhagen et al., 2006); and ID-Pain, identify Pain (Portenoy, 2006). The sensitivity (66–91%) and specificity (74–94%) of these tools fall within reasonable ranges in adults (Bennett et al., 2007; Haanpaa et al., 2009) but they have not yet been validated in children.
- ♦ Pain history including: evaluation of intensity (assessed by numerical rating scale or visual analogue scale), quality (sensory descriptors), temporal aspects of pain (frequency, spontaneous/paroxysmal or continuous, aggravating/relieving factors), and response to treatment. History remains the mainstay of diagnosis, and many children use descriptors that are considered 'typical' of NP, such as burning, shooting, radiating, burning, electricity-like, pain on contact, stabbing, pricking, tingling, pins and needles, and pinching (Krane and Heller, 1995; Wilkins et al., 1998, 2004). However, young children may be unable to clearly describe their pain in these terms.
- ♦ Sensory examination to verify the lesion of the somatosensory system (sensory, motor, and autonomic signs; allodynia and

**Table 21.1** Neuropathic pain conditions in children

Classification	Examples
Trauma	<ul style="list-style-type: none"><li>◆ Post surgery</li><li>◆ Phantom limb pain</li><li>◆ Brachial plexus injury</li><li>◆ Peripheral nerve injury</li><li>◆ Spinal cord injury</li></ul>
Complex regional pain syndrome	<ul style="list-style-type: none"><li>◆ Following trauma/fracture</li><li>◆ No precipitating cause</li></ul>
Neurological and neuromuscular disease	<ul style="list-style-type: none"><li>◆ Guillain–Barré disease</li><li>◆ Trigeminal neuralgia</li><li>◆ Multiple sclerosis</li></ul>
Metabolic disease	<ul style="list-style-type: none"><li>◆ Fabry’s disease</li></ul>
Neuropathy following infection	<ul style="list-style-type: none"><li>◆ HIV/AIDS</li><li>◆ Post-herpetic neuralgia</li></ul>
Tumour	<ul style="list-style-type: none"><li>◆ Nervous system tumour (neurofibromatosis)</li><li>◆ Invasion/compression by tumour</li><li>◆ Effect of treatment (e.g. post surgery, chemotherapy)</li></ul>
Genetic	<ul style="list-style-type: none"><li>◆ Erythromelalgia</li><li>◆ Paroxysmal extreme pain disorder</li></ul>

hyperalgesia; hypoaesthesia and hypoalgesia). Sensory abnormalities on clinical examination are more difficult to elicit in infants and young children. Quantitative sensory testing evaluates patterns of change in association with NP in adults (Maier et al., 2010), but paediatric use of this technique is often limited to research studies (Lebel et al., 2008; Sethna et al., 2007; see also Hermann, Chapter 40, this volume).

- ◆ Assessment of disability, quality of life, sleep, and mood. In adults, NP is associated with a greater disease burden than other forms of chronic pain, with effects on quality of life, impaired sleep, higher anxiety/depression scores, and increased use of health care and specialist services (Attal et al., 2011; Smith and Torrance, 2012). The impact of chronic pain on quality of life, mood, and disability is covered in many chapters throughout this text, but relatively few paediatric series have evaluated the impact of NP per se on quality of life (Jan and Wilson, 2004).
- ◆ Additional tests may be indicated, although many are limited to research settings or specific cases (e.g. electroneuromyography, microneurography, functional brain imaging, skin biopsy). Investigations may be required to confirm a specific underlying diagnosis (e.g. Fabry’s disease) or to exclude other causes.

**Neuropathic pain following trauma and surgery**

Laboratory models of traumatic peripheral nerve injury have demonstrated a reduced susceptibility to neuropathic pain if the injury is performed at a younger age (first 3 postnatal weeks in the rodent; see Vega-Avelaria and Beggs, Chapter 7; Walker, Chapter 3, this volume). Clinical studies are also suggestive of an increased likelihood of neuropathic pain following trauma or surgery at older ages.

**Post-surgical neuropathic pain**

Neuropathic pain can occur acutely or as a feature of persistent post-surgical pain in adults (Kehlet et al., 2006; Macintyre et al., 2010). There has been limited prospective evaluation of postoperative NP in children, and most data comes from retrospective questionnaires.

The largest study (response rate 63%, n = 651) surveyed 18- to 19-year-olds who had undergone inguinal hernia repair before 5 years of age (Aasvang and Kehlet, 2007). Pain from the operated groin was reported by 13.5% of respondents; 5.2% had pain at rest with an average intensity of 2.5 (range 1–9 on 0–10 visual analogue scale, VAS); and in 2% pain was frequent and moderate or severe (VAS 6.3, range 4–9). Neuropathic descriptors were reported by 53% and sensory descriptors by 72%, including tender, annoying, and shooting. There was no difference in incidence if surgery was performed before 3 months of age. Pain was frequently precipitated by exercise and activity, and this led the authors to conclude that a significant component of the pain may arise from muscle and/or ligamentous sources rather than being predominantly neuropathic pain.

Eighty-eight of 91 patients who underwent thoracotomy for repair of coarctation of the aorta between 1965 and 1985 at ages between 0 and 25 years were assessed at an average time of 39.3±7.7 years following surgery (Kristensen et al., 2010). An increased proportion reported pain for greater than 3 months following their surgery if it was performed at a later age: 1/31 at 0 to 6 years; 7/36 at 7 to 12 years, and 6/21 at 13 to 25 years. Three patients, who had initial surgery between 7 and 25 years, still reported pain with neuropathic descriptors at the surgery site. As the authors noted, this retrospective study is subject to significant recall bias, particularly for those who had surgery before 6 years of age.

Neuropathic pain was reported in six children (within a group of approximately 40) with cerebral palsy undergoing multilevel surgery to reduce contractures (tendon release/lengthening/transfer) and/or improve sitting position or gait. Pain with neuropathic descriptors commenced 4 to 9 days after surgery, was associated with allodynia in five of six patients, and required referral and ongoing management in a chronic pain clinic (Lauder and White, 2005).

Early-onset localized pain in surgical scars was reported in three cases following surgery at 14 to 17 years. Symptom onset was delayed for 6 to 12 months in a further two cases following surgery at 8 and 10 years respectively (Nayak and Cunliffe, 2008).

Ulna nerve injury with sensory and/or motor signs occurred in 6% of children (average age 6.5 years) having pins inserted for supracondylar fractures of the humerus. Recovery occurred after a mean of 9.3 (range 6–36) weeks, but the presence or absence of associated NP was not specifically reported (Eberl et al., 2011).

In summary, neuropathic pain can occur following surgery in children, but additional larger studies are required to evaluate the prevalence and duration of symptoms, and also determine if susceptibility is related to age at time of surgery.

**Phantom limb pain**

Altered sensory function following limb amputation is generally classified as non-painful phantom sensations or phantom limb pain. The majority of current literature is based on retrospective case series with differing methodology and variable response rates (Table 21.2).

**Characteristics of phantom pain**

Pain that is experienced in the region of the missing limb following amputation (i.e. phantom limb pain) has been described by

**Table 21.2** Studies on phantom pain in children

Study	Pain incidence overall + subgroups	Sensation incidence	Identified patients	Number	Age
Krane and Heller, 1995	Overall: 83%; 1/2 congenital deformity; 9/10 cancer; 10/12 trauma/infection	100%	Medical records 2 hospitals; amputations between 1980 and 1990; children <19 years age	n = 24; (54 mailed; 12 undelivered) 24/42 = 57% RR	Current age: 5–19 yrs; Age at operation 2–16 yrs Time since op. 1 mth–7 yrs

Thomas et al., 2003	Overall: 38%; major burn injury 20% (3/15) flame 53% (10/19) electrical		Retrospective medical record review; single hospital ~1972–2002	n = 34 (39 cases, 4 died, one major neurological injury)	Age at amputation: median 11 yrs (3–22 yrs)
Melzack et al., 1997	4% (3/75) congenital deficient; 22% (11/49) amputation <6 yrs	20% (15/76) congenital deficient; 50% (26/49) amputation <6 yrs	Recruit from Canadian Child Amputee Program (CHAMP) and single hospital	n = 125 (184/329 questionnaires returned; 46 interviewed at hospital; 125 met inclusion criteria)	Age at assessment: 14.7 yrs
Burgoyne et al., 2012	Overall: 76%; 26 cancer (20/26 primary bone tumours)		Retrospective medical record review; single hospital 2000–2007	n = 26 (2 excluded based on age 5/12 and 2 yrs old)	Age at assessment: 6 to 27 yrs; (median 15 yrs; 9/26 >18 yrs)
Smith and Thompson, 1995	Overall: 44%; 48% (32/67) cancer; 12% (1/8) trauma		Retrospective medical record review; single hospital 1983–1993	n = 75 (293 records reviewed, 75 met inclusion criteria)	5–17 years

children as sharp, tingling, stabbing, pins and needles, throbbing, piercing, squeezing, tight and uncomfortable (Krane and Heller, 1995; Wilkins et al., 1998, 2004).

Phantom pain is frequently of moderate or severe intensity, with reported mean ratings of  $5.29 \pm 2.4$  (Wilkins et al., 1998) and  $6.4 \pm 1.8$  out of 10 (Wilkins et al., 2004). Typically, pain is episodic, lasts for seconds or minutes, with a frequency varying from daily to monthly, and only a small proportion of children have reported constant pain (Wilkins et al., 2004).

Exercise, objects approaching the stump, cold weather, and 'feeling nervous' have been reported to trigger episodes of phantom pain (Wilkins et al., 1998). Psychosocial triggers were more common in girls, whereas pain was triggered by physical stimuli in a higher proportion of boys (Wilkins et al., 2004).

Phantom pain has been reported to produce minimal interference with daily activity (Wilkins et al., 1998). In a series of 88 children, five of 24 following lower limb amputation and one of 64 with congenital lower limb deficiency reported phantom pain, but 89% were able to use their prosthesis for the whole day; 95% were able to walk; and 93% of those over 4 years were able to cycle (Boonstra et al., 2000). It is not clear from this series if phantom pain influenced the ability to tolerate the prosthesis, but it has been reported that phantom limb sensations were less apparent while wearing a prosthesis (Melzack et al., 1997).

### Associated phenomena

Non-painful sensations experienced in the region of the missing limb (i.e. phantom sensations) are reported by 50% to 100% of children following surgical amputation and in 7% to 20% of children with congenitally deficient limbs (Table 22.2). These have been described as tingling, pins and needles, tickling, 'feels asleep',

numb, itching, and prickling (Krane and Heller, 1995; McGrath and Hillier, 1992; Wilkins et al., 1998, 2004). Despite reported mean intensities of 4 to 5 (0 = no sensation, 10 = strongest imaginable sensation), phantom sensations had minimal impact on daily activities (Wilkins et al., 1998, 2004).

Stump pain often coexists with phantom limb pain but may also occur in isolation. A higher incidence has been reported following surgery than in children with a congenitally absent limb (Wilkins et al., 1998, 2004).

### Incidence of phantom limb pain

It is now well established that NP can follow amputation in children, but it is difficult to accurately estimate the incidence. Much of the data comes from retrospective questionnaires with response rates below 50% or from medical case notes that may not accurately record all symptoms. Samples are often small, may be derived from the community or clinics, and the duration between surgery and assessment is often variable.

Reported incidences of phantom limb pain are summarized in Table 21.2. Factors that have been associated with an increased incidence in children include:

- ♦ Surgical amputation (49–76%) versus congenitally deficient limbs (3–4%).
- ♦ Older age at time of amputation. A negative correlation has been reported between age at disruption and onset of a phantom limb (i.e. amputation at older age, shorter time to phantom onset) but it is not clear if this relationship holds for phantom pain as well as phantom sensations (Melzack et al., 1997)
- ♦ Cancer and chemotherapy. Phantom pain following amputations for cancer has been reported in 48–90% of children (Burgoyne

et al., 2012; Krane and Heller, 1995), and in one small series the rate was higher than following amputations for trauma (32/67 versus 1/8; Smith and Thompson, 1995). Chemotherapy may also increase the risk of phantom pain as the incidence ranged from 74% in children exposed to chemotherapy before or at the time of amputation, to 44% if chemotherapy was only administered after the amputation, and was lowest (12%) in those who did not require chemotherapy (Smith and Thompson, 1995). Other causes of cancer-related neuropathic pain are discussed later in the chapter.

- ♦ Major burns due to electrical (10/19) versus flame (3/15) injury (Thomas et al., 2003).
- ♦ Preoperative pain. The presence of pain prior to amputation was reported in 35% to 75% of patients who developed phantom pain (Krane and Heller, 1995; Wilkins et al., 1998). The impact of preoperative pain on the incidence or degree of phantom pain has not been assessed in children, although in one series both patients with the most persistent pain had also experienced pain prior to amputation (Burgoyne et al., 2012)

### Time course

Onset of pain in the early postoperative period was reported in 85% (Krane and Heller, 1995) and 53% (Wilkins et al., 1998) of children with phantom pain, within weeks or months in 20% or 30%, and in one patient from both series the onset of pain was delayed for more than a year. An earlier onset of phantom pain (mean 6 days versus 12.3 days) was noted in children receiving perioperative chemotherapy (Smith and Thompson, 1995). The mean time to onset of phantom limb sensations was 2.3 years in children with surgical amputation before 6 years, and 9 years in those with a congenitally absent limb (Melzack et al., 1997).

There is a perception that phantom limb pain resolves more rapidly in children than in adults, but there is limited supporting evidence. Phantom pain is often poorly documented in medical case notes (Krane and Heller, 1995), and there has been little prospective follow-up, although in a single case a progressive reduction in the duration, frequency and intensity of phantom pain episodes was noted over the first 28 postoperative days (McGrath and Hillier, 1992). In 20 children requiring amputation for cancer, trauma or infection, pain reduced in intensity and frequency in 13 (with resolution after months in two and years in four), but was unchanged in seven (Krane and Heller, 1995). Phantom limb pain was documented in the charts of 19 of 25 patients (age 6 to 27 years) after cancer-related amputation, and only two patients (both of whom were older than 18 years and had pain prior to the amputation) still had pain at 1 year (Burgoyne et al., 2012).

### Obstetric brachial plexus injury (OBPI)

The brachial plexus innervates the upper limb and is formed from the lower cervical (C5,6,7,8) and the first thoracic (T1) nerve roots. Obstetric complications, such as shoulder dystocia or breech delivery can be associated with traction injuries of the brachial plexus injury in the newborn. The associated nerve lesions range in degree from neuropraxia to complete root avulsion, and can affect part or all of the plexus. Surgical exploration and repair, where possible, is often performed if there is no spontaneous recovery or elbow flexion by 3 to 6 months (Malessy and Pondaag, 2011). Associations between OBPI and pain in later life have been assessed in a number of series, which vary in the outcomes measured and the time since injury.

In addition, it is difficult to differentiate neuropathic pain associated with the initial injury from pain related to: re-innervation following early microsurgical repair and nerve grafts; subsequent surgical procedures (e.g. tendon transfers or rotational osteotomies) that may be required throughout childhood to improve function; trophic injuries associated with reduced sensory function; and musculoskeletal pain. These issues are highlighted by the following case series.

- ♦ Twenty-four patients with OBPI (20 operated and four non-operated) were assessed at intervals ranging from 3 to 23 years. Neither patients nor parents reported symptoms suggestive of neuropathic pain in the affected limb. Pain in a scar associated with surgery at 4 years was reported in one case. Restoration of sensory function and accurate stimulus localization was documented in 16/20 following microsurgical repair (Anand and Birch, 2002).
- ♦ A retrospective chart review of OBPI cases between 1990 and 2002 noted self-mutilating behaviour in 3.9% (11/280) of infants (McCann et al., 2004), which may be a response to sensory loss, and/or painful dysaesthesias in a hypoaesthetic or reinnervated area. The incidence was influenced both by the occurrence and the type of prior surgery; increasing from 1.4% (2/147) in the non-surgical group, to 6.8% (9/133) in those who had surgery prior to developing self-mutilating behaviour. Within the surgical group, the rate was much higher in association with microsurgery involving the plexus (29.1%; 7/24) than following bone or tendon surgery (1.8%, 2/109). The median onset 8 months after surgery and resolution of behaviour 4 to 7 months later also suggest a time course related to re-innervation dysaesthesia in at least some patients.
- ♦ A survey of 53 7- to 8-year-old children with OBPI (61% response rate) reported pain in the shoulder, upper arm and neck, particularly during writing, in 45% of children. The authors attributed pain to musculoskeletal causes (Spaargaren et al., 2011).
- ♦ Pain in the affected upper limb was reported by 31% of 112 patients, on average 13.5 (range 5.6–31.5) years after OBPI. In nine patients, local pain was associated with non-union of the clavicle (divided to improve access during initial surgery). It is not clear if patients had features suggestive of neuropathic pain, related either to the initial or to subsequent injuries which were relatively common (11% burns, 15% other injuries; Kirjavainen et al., 2008). Persistent neuropathic pain was reported in one of 70 patients with OBPI, now aged 7 to 20 years. 'Most participants' reported discomfort in the arm, usually in the shoulder or elbow after exercise. Quantitative sensory testing demonstrated reduced thermal sensitivity in 16% of patients, but as seen in other studies, there was better recovery of sensory than motor function (Strombeck et al., 2007).

### Trauma during childhood

#### Brachial plexus injury during childhood

Trauma during childhood can result in brachial plexus injury (BPI), but the number of reports and details of associated pain are limited. Ten children aged 3 to 16 years had BPI and fractures following motor vehicle accidents. Reconstructive surgery was performed 1 to 8 months later, and there were no reports of deafferentation pain (El-Gammal et al., 2003). In a further 25 cases of traumatic BPI (2/12 to 14 years) related to motor vehicle accidents, 16 required plexus exploration and several subsequent orthopaedic procedures. Two teenagers with root avulsions complained of moderate pain, but there are no further details of the nature or time

course of symptoms (Dumontier and Gilbert, 1990). By contrast, BPI in association with proximal humerus fracture in four patients (10–14 years), was associated with neurological recovery by 5 to 9 months, but all had NP (often described as burning) for at least 6 months (Hwang et al., 2008).

### Peripheral nerve injury

A series of 49 children with distal upper limb nerve injury were followed for an average 2 years and 3 months (Atherton et al., 2008). As seen following amputation, an increased proportion of older children developed neuropathic symptoms. No children under 5 years (0/15) had pain or allodynia, whereas the five children with spontaneous pain were all aged over 12 years at the time of injury. A further eight children aged older than 5 years had increased sensitivity to thermal or pinprick stimuli (Atherton et al., 2008).

### Spinal cord injury (SCI)

Pain after SCI in adults is classified as nociceptive (musculoskeletal, visceral, other) or neuropathic (Bryce et al., 2012), with the latter categorized as:

- ♦ ‘At level SCI pain’ occurring in a segmental pattern within three dermatomes of the neurological level of the injury, and likely due to injury to the nerve roots and/or cord.
- ♦ ‘Below level SCI pain’ occurring more than three dermatomes below the neurological level of injury, which is a result of damage to the spinal cord, and can occur following either complete (no motor function preserved below the level) or incomplete injuries.
- ♦ Other coexistent causes of NP not related to the spinal lesion (e.g. trigeminal neuralgia).

Only 3% to 5% of new cases of SCI are in children, but SCI can occur in neonates as a complication of delivery, and tends to have a better recovery than seen at older ages (Pape, 2012). Complete cord lesions are more common in younger age groups, and there is a male predominance at all ages. Follow-up an average of 15 years following SCI (mean age at injury 14 years,  $n = 216$ ) reported an overall incidence of pain at any site of 69%, with younger age at injury associated with orthopaedic complications such as scoliosis and hip subluxation, and older age at injury associated with ankle pain and spasticity (Vogel et al., 2002). NP has been reported to be less common if injury occurs at a younger age: 26% (24/91) before 20 years of age versus 45% (139/311) at older ages (Werhagen et al., 2004). In a series of 31 participants, aged between 5 months and 18 years at the time of SCI, 65% reported chronic pain, and this had neuropathic features in 19%, but was associated with less interference in daily activities than in adults (Jan and Wilson, 2004).

## Cancer-related neuropathic pain

Neuropathic pain occurs in 20% to 40% of adult patients with cancer (Bennett et al., 2012). The overall rate of cancer-related neuropathic pain is likely to be lower in children, but as noted earlier phantom limb pain is more common in children who require amputations for cancer and perioperative chemotherapy. Significant pain may occur in specific populations:

- ♦ *Primary tumours* within the nervous system. Neurofibromatosis type 1 (NF1) and type 2 (NF2) are neurocutaneous disorders associated with tumours affecting the central and peripheral nervous systems (Ardern-Holmes and North, 2011; Jett and

Friedman, 2010). Pain is experienced by up to 46% of children with plexiform neurofibromas (Serletis et al., 2007), and increasing pain and rapid growth of the tumour may indicate development of a malignant nerve sheath tumour (Ardern-Holmes and North, 2011). Pain can also have significant impact on health-related quality of life in children with NF (Krab et al., 2009) and this condition is also discussed by Mherekumombe and Collins (Chapter 32, this volume).

- ♦ *Tumour invasion or compression* of neural structures (spinal cord, spinal nerve roots, nerve plexus, peripheral nerves). As the incidence of solid tumours is lower in children, tumour invasion/compression is less common in children than in adults, but can result in severe pain with high analgesic requirements. Pain may be difficult to control with opioids alone, and in some cases requires regional blockade with local anaesthetic (Butkovic et al., 2006; Collins et al., 1995; Cooper et al., 1994).

## Cancer treatment-related neuropathic pain

Treatment-related NP may occur following surgery (e.g. post-amputation pain; see ‘Phantom limb pain’ section) or chemotherapy. Perioperative chemotherapy has also been associated with an increased incidence and earlier onset of post-amputation pain (Smith and Thompson, 1995).

Peripheral neuropathy occurs in 50% to 90% of those treated with platinum compounds (cisplatin) and almost half with vinca alkaloids (vincristine; Vondracek et al., 2009). In 21 children with solid tumours and nine with leukaemia aged between 10 and 17 years, neuropathic pain symptoms (paraesthesia, numbness and burning pain in the fingers and toes, hyperalgesia and tactile allodynia) commenced within days of beginning chemotherapy. In addition, pain was severe (mean baseline VAS >75/100) (Vondracek et al., 2009). In a retrospective review, 174/498 patients developed peripheral neurotoxicity with vincristine treatment for acute lymphoblastic leukaemia (Anghelescu et al., 2011). Associated NP occurred in 35%, with recurrent episodes in 16% to 30.6%. Age at diagnosis ranged from 1 to 19 years, but had minimal influence on the rate of NP, which varied from 31% in the 1- to 5-year-group, to 40% in those aged 16 to 20 years. Pain was described as aching, burning, cramping, tingling, numbness, sharp, or stinging; and was most common in the lower limbs, back and jaw (Anghelescu et al., 2011).

Treatment of high-risk neuroblastoma with a monoclonal antibody directed against the tumour-associated disialoganglioside GD2 can result in severe acute pain in children (Wallace et al., 1997; Yu et al., 2010). Laboratory studies have confirmed mechanical allodynia as a result of C-fibre activation (Xiao et al., 1997) and complement activation (Sorkin et al., 2010), which is reduced by gabapentin (Gillin and Sorkin, 1998). Current clinical treatment protocols incorporate NP management strategies, such as oral gabapentin, and addition of intravenous ketamine or lidocaine if pain is inadequately controlled by intravenous opioid (Wallace et al., 1997; see also Rastogi and Campbell, Chapter 48, this volume).

## Metabolic disorders

### Fabry’s disease

#### Clinical features

Pain is a common presenting symptom in Fabry’s disease, and often has an onset during childhood (Hoffmann et al., 2007;

Pintos-Morell and Beck, 2009; Ries et al., 2005). As pain may be the only feature for some years, Fabry's disease should be considered in the differential diagnosis of pain clinic referrals (Pagnini et al., 2011). Episodic burning pain and 'pins and needles' may initially be restricted to the hands and feet, but pain becomes more persistent and generalized with time (Hoffmann et al., 2007) and can be triggered by changes in environmental or body temperature, exercise, or emotional stress (Ries et al., 2005). Pain is not only present in over 70%, with a higher incidence in males (80% versus 65%; Hoffmann et al., 2007), but it has a significant impact on quality of life (Ramaswami et al., 2006; Ries et al., 2005). Other features of Fabry's disease include hypo- or hyperhidrosis, gastrointestinal disturbances and abdominal pain, angiokeratomas, and ophthalmological abnormalities (cornea verticillata) (Mehta et al., 2010; Ramaswami, 2008).

### Pathophysiology

Fabry's disease is an X-linked recessive disorder, and females typically have less severe symptoms that develop at a later age. Mutations in the *GLA* gene that encodes the lysosomal enzyme alpha-galactosidase A result in failure to catabolize lipids containing alpha-D-galactosyl moieties. Accumulation of glycolipids, including globotriaosylceramide (Gb3) in cells and tissues results in dysfunction of multiple organ systems including heart, kidney, gastrointestinal tract, and nervous system (Hoffmann et al., 2007). Small fibre loss in peripheral tissues and glycolipid accumulation in the dorsal root ganglia or nerves may underlie the neuropathic pain symptoms (Borsook, 2012).

### Age

Reported ages at diagnosis range from 5 to 77 years (Pagnini et al., 2011). However, pain has been reported from 3 years of age in boys and 6 years in girls, with neuropathic features at a mean age of  $7.8 \pm 3.2$  years (Ries et al., 2005). Similarly, neuropathic pain was reported in 59% of boys (median 7 years) and 41% of girls (median 9 years) (Hopkin et al., 2008).

### Diagnosis and management

The diagnosis is based on measurement of plasma alpha-galactosidase A activity (although levels may be normal in carrier females), and of plasma or urinary Gb3 or lyso-Gb3; and is confirmed by genetic analysis of *GLA* gene (Mehta et al., 2010).

Enzyme replacement therapy with alpha-galactosidase A reduces glycolipid storage in tissues, but effects on pain take time. Improvement in all dimensions of pain perception after 24 months has been reported (Hoffmann et al., 2007), with reductions in neuropathic 'pain at its worst' scores in both boys and girls (2.8 to 1.5) and 'average pain' from 2.2 to 0.9, and a reduced requirement for neuropathic treatment with anti-convulsants (Pintos-Morell and Beck, 2009). In others, the overall prevalence of pain was not altered by enzyme replacement therapy, but those with pain at the onset of therapy did show a decrease in severity (Ramaswami et al., 2011).

## Neurological disorders

Neuropathic pain is a feature of several neurological conditions. Pain associated with neurofibromatosis, Guillain-Barré syndrome, neuromuscular disorders and pain associated with HIV are covered by Mherekumombe and Collins (Chapter 32, this volume).

## Multiple sclerosis

Multiple sclerosis (MS) is a chronic inflammatory disease producing demyelination and axonal damage in the brain and spinal cord (Mariotti et al., 2010). Pain is common in adults with a prevalence from 57% to 65%, and 43% to 54% have pain at the time of diagnosis. Patients with MS may experience multiple types of pain (including tonic spasms, back pain, and headache) but additionally may experience central neuropathic pains.

- ♦ Dysaesthetic extremity pain occurs in up to 23% of patients. Pain is burning, typically bilateral, often in the legs and feet, worse at night, and is exacerbated by exercise.
- ♦ Trigeminal neuralgia is more common than in the general population with a higher rate of bilateral symptoms.
- ♦ Brief electric shock sensations in the back of the neck, lower back, or other parts of body, are brought on by neck flexion (Lhermitte's sign).

An estimated 2% to 5% of patients experience their first symptoms of MS before 16 years of age, with onset usually between 8 and 14 years, and a higher incidence in females (ranging from 1.3 to 3 times). Cohorts of paediatric MS patients report sensory symptoms in 13% to 69%, but there is little information about the proportion with neuropathic pain (Ness et al., 2007). Headache is more frequent in paediatric than in adult patients with MS (Mariotti et al., 2010). The course of the disease may be slower in children, but can have a significant impact on schooling and psychosocial function (Ness et al., 2007); further reductions in quality of life have been associated with increasing age and duration of illness. The impact of disease-modifying therapies, such as interferon, on pain symptoms are not clear (O'Connor et al., 2008).

## Postherpetic neuralgia

Reactivation of varicella zoster virus infection, which has been dormant within sensory neurons, results in painful eruptions along the distribution of the nerve (also known as shingles), and approximately 14% of adults develop persistent neuropathic pain (i.e. postherpetic neuralgia, PHN; Delaney et al., 2009). Overall, zoster infection and PHN are less common in children (Hall et al., 2006), but children who are immunocompromised, particularly in association with cancer treatment, are at higher risk. In a series of 226 children with acute lymphoblastic leukaemia, zoster eruptions occurred 90 times, with recurrent episodes in 14 children. All experienced pain with the acute eruption and were treated with acyclovir, and five developed postherpetic neuralgia, which persisted for greater than 2 months in two patients (Sorensen et al., 2011).

## Trigeminal neuralgia

### Clinical features

Clinical features of trigeminal neuralgia include (Bender et al., 2011; Solth et al., 2008; Yue, 2004):

- ♦ Unilateral pain in the distribution of the trigeminal nerve. The trigeminal innervation is divided into three zones: V1 ophthalmic (scalp, forehead, upper eyelid, eye), V2 maxillary (lower eyelid, cheek, nose, upper teeth and gums), and V3 mandibular (lower teeth and gums, jaw, parts of external ear). Pain may be experienced in one or more zones—most commonly V2 followed by V2/3 combined.

- ♦ Pain is described as sharp, lancinating or shooting, electric-shock like, and occasionally burning.
- ♦ Pain is intermittent and paroxysmal.
- ♦ Intermittent paroxysms of pain can be triggered by light touch in the trigeminal region (cutaneous trigger zones), chewing, brushing the teeth, cold wind, or exercise.

Pain may also be associated with spasm of the facial muscles, or *tic douloureux*.

### Incidence

The incidence of trigeminal neuralgia is much lower in children (Hall et al., 2006), and less than 1.5% of patients with trigeminal neuralgia report an onset of symptoms before 18 years of age (Bender et al., 2011). Case series report trigeminal neuralgia in children aged from 3 to 18 years, with median ages of 11 to 13 years (Bender et al., 2011; Resnick et al., 1998; Yue, 2004).

### Pathophysiology

Trigeminal neuralgia may be classified as idiopathic or result from compression within the intracranial course of the nerve either by vasculature (Bender et al., 2011; Resnick et al., 1998; Solth et al., 2008) or by tumour (da Silva et al., 2006). As idiopathic trigeminal neuralgia and glossopharyngeal neuralgia (pain in the posterior tongue, pharynx, beneath angle of lower jaw and/or in ear) are rare in children, appropriate imaging and investigations are required to exclude underlying causes (Arruda et al., 2011). A 1-year-old child who presented with episodic crying and raising the hand towards the left ear, had marked allodynia over the ear, and was found to have a schwannoma in the trigeminal nerve (da Silva et al., 2006).

## Neuropathic pain and genetic disorders

### Erythromelalgia

#### Clinical features

Erythromelalgia (EM) is characterized by severe episodic pain and redness affecting the hands and feet (Waxman and Dib-Hajj, 2005). Bilateral pain and redness of the ears may also represent a variant of EM (Brill et al., 2009; Vivas et al., 2011). Pain is aggravated by warmth, prolonged standing and exercise, and relieved by cooling and submersion in iced water, but is often poorly responsive to analgesia.

#### Pathophysiology

The pathophysiology of EM has been attributed to vascular, inflammatory and neuropathic causes (Waxman and Dib-Hajj, 2005). Both microvascular ischaemic (vasoconstrictive) and reactive-hyperaemic (vasodilatory) subtypes have been postulated, resulting in treatment with a wide range of vasoactive drugs (Cohen, 2000). EM has also been reported in association with myeloproliferative or auto-immune disorders, and in such cases may be termed secondary EM (Novella et al., 2007).

Primary EM has recently been associated with a genetic mutation, which may occur spontaneously, or in association with a positive family history. Nine subtypes of voltage gated sodium channels have been identified ( $\text{Na}_v1.1$  to  $\text{Na}_v1.9$ ).  $\text{Na}_v1.7$  is of particular importance for pain as it is selectively expressed within nociceptive dorsal root ganglion and sympathetic ganglion neurons (Dib-Hajj et al., 2009; Drenth and Waxman, 2007; Fischer and Waxman, 2010). Mutations in the *SCN9A* gene, which encodes the  $\text{Na}_v1.7$  channel, can result in either:

- (1) Loss of function and congenital insensitivity to pain (Cox et al., 2006; Staud et al., 2011), or
- (2) Gain of function and increased pain (Cummins et al., 2007; Dib-Hajj et al., 2005; Waxman and Dib-Hajj, 2005). Point mutations at different sites result in two distinct phenotypes: paroxysmal extreme pain disorder (PEPD) or primary EM (Cheng et al., 2010; Fertleman et al., 2006; Estacion et al., 2008). Mutations associated with EM alter channel activation, reduce threshold and increase firing frequency, and increase excitability.

### Age-dependent effects

The degree of change in channel kinetics varies with the site of the mutation, and larger depolarizing shifts have been associated with onset of symptoms at younger ages (Ahn et al., 2010; Han et al., 2009). However, variable expression of neonatal and adult isoforms of the channel may also influence the age at which symptoms first appear (Choi et al., 2010).

### Management

Diverse views of the pathophysiology of EM have resulted in a range of treatments directed at vascular (vasoactive drugs such as topical GTN, sodium nitroprusside infusion, clonidine; Cohen, 2000), anti-inflammatory, and neuropathic aetiologies (amitriptyline, gabapentin; Natkunarajah et al., 2009). With awareness of the potential involvement of  $\text{Na}_v1.7$  in EM, there has been increased use of drugs with sodium channel blocking activity. Different EM-related mutations may be more responsive to either mexiletine (Choi et al., 2009; Iqbal et al., 2009; Nathan et al., 2005) or carbamazepine (Fischer et al., 2009).

### Paroxysmal extreme pain disorder

PEPD can present soon after birth with episodic pain in association with redness over the buttocks, legs and feet. Through infancy and childhood, the condition progresses to include episodes of (Fertleman et al., 2006):

- ♦ Rectal pain, often induced by a bowel movement, and burning pain and redness in the lower limbs.
- ♦ Brief episodes of intense burning ocular pain associated with redness around the eyes and runny nose and eyes.
- ♦ Bilateral mandibular pain and redness, which may be triggered by cold, eating or emotional state.

Mutations at different points in the *SCN9A* gene result in altered channel kinetics (impaired inactivation, prolonged action potential, and repetitive firing) and a phenotype that differs from EM (Estacion et al., 2008). PEPD has been reported to be differentially sensitive to carbamazepine (Fertleman et al., 2006).

## Conclusion

Neuropathic pain is a frequent reason for referral to a paediatric chronic pain clinic, and diagnosis is predominantly based on the pain history and descriptors. NP following trauma is more common when the initial injury occurs later in childhood (e.g. following amputation at greater than 6 years). However, NP can occur at younger ages, particularly in higher-risk populations (e.g. cancer, chemotherapy and immunosuppression) or in association with specific conditions (e.g. Fabry's disease). Pharmacological

management of NP is largely extrapolated from adult studies (see Rastogi and Campbell, Chapter 48, this volume). However, pain is often severe and only partially responsive to pharmacological interventions, and multidisciplinary care is required. As discussed in other chapters throughout this text, assessment and management of chronic pain (including NP) must also encompass non-pharmacological and psychological interventions, include family or caregivers, and address issues related to poor sleep and school attendance.

### Case example

A 10-year-old boy with severe vascular malformations of the lower leg has had multiple episodes of infection and of bleeding requiring transfusion and now presents for a below-knee amputation. Preoperative preparation has included discussions with rehabilitation specialists and psychologists, and his perioperative pain management has been planned in coordination with the anaesthetist, pain service, and surgical team. As there are no contraindications, consent is gained for epidural catheter insertion and an infusion of local anaesthetic and opioid is commenced immediately prior to surgery and continued for the first 3 postoperative days, with good control of pain. Following cessation of the epidural he develops a sensation of a larger than normal lower leg which is pointing down through the bed at an unusual angle. In addition, he has paroxysms of shooting pain extending below the stump, which are not relieved by oral opioids, and which are significantly disrupting his sleep. He is commenced on oral amitriptyline at night and oral gabapentin. The episodes of pain become less frequent, but remain severe, and gradually improve with escalation of the gabapentin dose over the next 7 days. He is subsequently discharged for rehabilitation at a different centre, where he receives ongoing multidisciplinary care (that includes psychological and family support and input from the pain service) regarding management of his amputation, phantom limb pain, fitting of a prosthesis, and a gradual return to school is planned. Three months later he returns to the chronic pain clinic for review. He has occasional episodes of pain during the day, ongoing non-painful phantom sensations (although the size of the phantom has significantly reduced), and is sleeping well at night but feels a little drowsy in the morning. The amitriptyline is weaned without any increase in pain, and he continues to be reviewed with a plan to gradually wean the gabapentin as tolerated.

## CHAPTER 22

# Inflammatory arthritis and arthropathy

Peter Chira and Laura E. Schanberg

### Summary

Musculoskeletal pain is a common symptom in inflammatory arthritides such as juvenile idiopathic arthritis; however, identifying the underlying pathological process is often challenging for health care providers due to the extensive differential diagnoses. In children with inflammatory arthritides, physical examination abnormalities including swelling and/or pain on movement and joint limitation accompany the pain at initial presentation. Control of disease activity through anti-inflammatories and other disease-modifying agents can limit disease progression and joint damage; however, pain may persist in spite of these measures. Optimal treatment of pain in juvenile idiopathic arthritis and related conditions is based on a biopsychosocial model, which addresses biological, environmental, and cognitive-behavioural factors. Analgesics such as opioids and neuropathic pain medications, in conjunction with other modalities such as pain coping skills training, aerobic exercise, and improved sleep hygiene may be appropriate in certain circumstances. Further research is needed to prospectively identify patients and families early in the course of disease who would benefit from additional support to optimize pain management and limit distress. In addition, future clinical trials should assess the impact of study interventions on pain as a primary endpoint, assessed independently from other response variables.

### Introduction

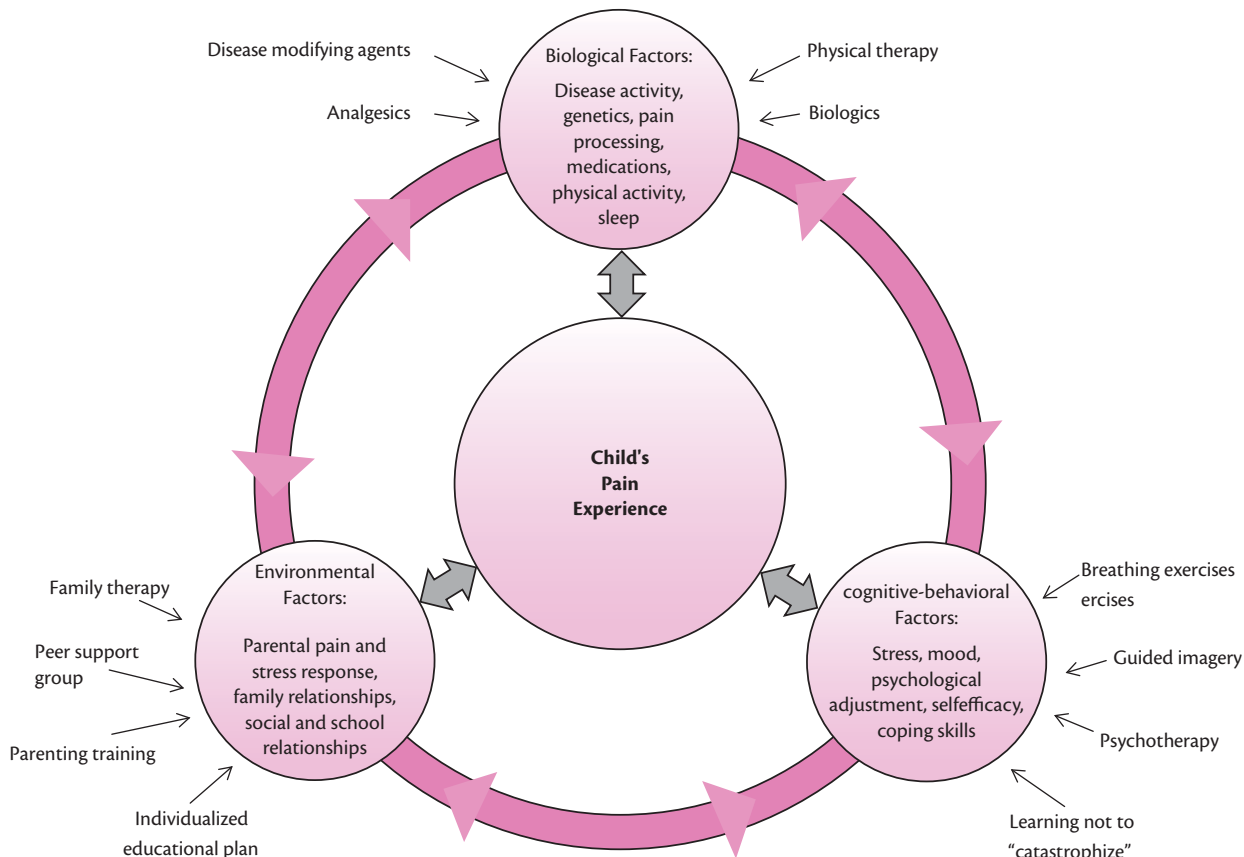

The evaluation of children with musculoskeletal pain is often challenging for health care providers due to the extensive differential diagnoses. Identifying any underlying pathological process in a thoughtful, expeditious manner is extremely important in order to minimize distress of patients and families and prevent long-term disability. Many practitioners lack comfort and familiarity in determining if musculoskeletal symptoms and pain complaints are related to an inflammatory process such as juvenile idiopathic arthritis (JIA) or other inflammatory disorders. Prompt recognition and diagnosis of an underlying rheumatic disorder allow for early treatment to reduce pain and other symptoms. Ideally, through treatment, long-term damage to joint or muscle is prevented, limiting physical disability and/or emotional distress. Additionally, control of inflammation may decrease pain signalling and prevent long-term alteration of

pain processing. However, aggressive medical therapy alone is not sufficient to optimally treat pain in children with rheumatic conditions. Other important concomitant factors besides disease activity impact pain perception and management. A biopsychosocial model of pain more completely addresses all factors contributing to the pain symptoms of a child with an underlying rheumatic disease, serving as an effective framework for treatment (Figure 22.1).

### Mechanisms of arthritis pain

Much of what is understood about the biology of joint pain comes from the study of neural pathways in mice models of experimental inflammatory arthritis (McDougall, 2006; McDougall and Larson, 2006). Schaible's extensive work on the basis of pain resulting from inflammatory arthritides such as rheumatoid arthritis (RA) and JIA (Schaible et al., 2002, 2005, 2009) have described two primary mechanisms: peripheral sensitization (increased sensitivity of nociceptive primary afferent neurons) and central sensitization (hyperexcitability of nociceptive neurons in the central nervous system). Degenerative processes within joints, along with inflammation, can trigger and exacerbate sensitization of pain pathways, resulting in the development and perpetuation of chronic pain. Current mechanistic theories behind the development of pain associated with inflammation and arthritis in children with rheumatic disease have been reviewed (Kimura and Walco, 2007).

Primary afferent neurons have three main functions in nociception: detection of noxious or damaging stimuli (transduction), conveyance of sensory input from the periphery to the spinal cord (conduction), and synaptic transfer of input to neurons within specific laminae of the dorsal horn of the spinal cord (transmission) (Kidd and Urban, 2001). C-fibre nociceptors are activated by thermal, mechanical, and chemical stimuli, and can also be sensitized by mediators of the inflammatory response (e.g. prostaglandin E<sub>2</sub> and bradykinin; see Walker and Baccei, Chapter 6, this volume). Once sensitization occurs, low-level previously non-noxious stimulation elicits neural activity (Giordano, 2006), and pain can be precipitated by routine movement in the presence of inflammation or joint damage from trauma or tissue injury. In inflammatory arthritis, a complex interplay of mechanical factors and chemical mediators such as release of bradykinins, prostaglandins, neuropeptides, cytokines, and ion channels is triggered, resulting in a decrease in

**Figure 22.1** Biopsychosocial model of pain. Arthritis pain has multiple factors (biological, environmental, and cognitive-behavioural) that can contribute to a child's perception of pain. Treatment strategies should address the various components that can include pharmacological and non-pharmacological therapies.

the normal pain threshold within a joint and causing hyperalgesia and allodynia in local tissues. Inflammatory cytokines such as tumour necrosis factor alpha (TNF- $\alpha$ ), interleukin 1, and interleukin 6 can directly activate nociceptors and contribute to effects of inflammation itself (via swelling affecting mechanical nociception), which helps to initiate and perpetuate the pain signal (Kidd and Urban, 2001; Oen et al., 2005). Thus, newer biological agents to control inflammatory arthritis using anticytokine therapies may impact arthritis pain directly, as well by decreasing disease activity.

Joint inflammation also produces central sensitization occurs when various neurotransmitters (e.g. L-glutamate) and neuropeptides (e.g. substance P, neurokinin A) activate and/or modulate synapses within the dorsal horn in the spinal cord, leading to enhancement of the pain signal and potential expansion of pain receptive fields via postsynaptic receptor activation (Schaible et al., 2009). Pain can be modulated by: reducing central sensitization via antagonism of postsynaptic receptors (e.g. N-methyl-D-aspartate (NMDA); Schaible et al., 2006); local inhibitory and excitatory interneuron circuits within the dorsal horn; as well as descending pathways (e.g. from the rostral medulla) that can facilitate or inhibit spinal nociceptive processing (Schaible et al., 2005). Imaging studies in adults have also shown that cortical processes have a major role in the mediation of pain processing that includes elements of cognition, arousal state, attention, and expectation (Seifert and Maihofner, 2009; see also Fitzgerald, Chapter 8; Hermann, Chapter 40, this volume).

Increasingly recognized as an important factor in the establishment of chronic pain is the role of accessory glial cells in the

perpetuation of pain signals (Milligan and Watkins, 2009; see also Vega-Avelaira and Beggs, Chapter 7, this volume). In inflammatory arthritides such as JIA, the role of glial cells in perpetuating pain is unclear but growing evidence suggests that cytokines released as part of the inflammatory cascade can affect and alter glial mediated central pain processing, resulting in dysfunctional pain signalling (Milligan and Watkins, 2009).

Chronic pain in children with rheumatic disease is the result of an integration of biological processes (e.g. glial cell activation, peripheral and central sensitization), psychological factors (e.g. anxiety, poor coping), and sociocultural contexts (e.g. parental emotional distress, peer relationships) within a developmental framework (Zeltzer et al., 1997). Disease activity and day to day life experiences, including emotional state, sleep quality, and family and peer relationships, all impact the severity, characteristics, and regularity of pain with time. Ongoing pain can result in sensitization of the peripheral and central nervous systems, producing neurophysiological, neurochemical, and neuroanatomical changes (Woolf and Salter, 2000), which may continue despite low disease activity or the absence of tissue damage. In addition, the extent of disability associated with a specific chronic pain level varies from person to person based on genetics as well as many of the biopsychosocial factors that impact pain perception. In summary, pain perception is multifactorial and best understood using a biopsychosocial framework including developmental status, coping ability, mood, stress levels, as well as environmental and family factors, in addition to disease status and severity (Rapoff and Lindsley, 2000).

## Clinical presentation

Children and adolescents presenting with rheumatic disease may not have musculoskeletal pain as their sole, primary presenting complaint. However, for children with chronic inflammatory arthritis, joint pain can be a major presenting symptom. Interestingly, McGee looked at all patients presenting to a paediatric rheumatology clinic, and of 111 patients with an initial chief complaint of isolated musculoskeletal pain, only one had arthritis or other rheumatic disease (McGhee et al., 2002). These findings confirmed earlier data, which showed that the majority of patients referred to paediatric rheumatology clinics across the US do not have primary rheumatic disease but rather non-specific musculoskeletal complaints or abnormal laboratory studies (such as a positive antinuclear antibody; Bowyer and Roettcher, 1996). Both studies highlight the need for health care professionals to distinguish those with non-specific musculoskeletal pain from those with inflammatory conditions.

When joint pain is the primary complaint for a patient presenting with inflammatory arthritis such as JIA, it is accompanied by overt abnormalities on examination such as swelling and/or pain on movement with limitation of motion, or tenderness noted at the joint line along with limitation. The pain of arthritis is typically described as mild to moderate, dull or achy discomfort, with joint stiffness that worsens with inactivity (sleeping or sitting for prolonged periods) and improves with movement. Pain at rest is unusual. Pain commonly varies from day to day; however, the physical examination abnormalities are constantly present. Often, the stiffness is described as a 'gel phenomenon' in which inactivity causes a sensation within the affected joint(s) similar to gelatin setting or glue drying, although the exact pathophysiology of why this occurs is not understood. Arthritis pain rarely causes night awakening; therefore, other causes of joint or bone pain must be ruled out including malignancy, infection, or bone tumours (osteoid osteoma) if night pain is the primary complaint. Other signs of chronic inflammatory arthritis include gait abnormality such as limp, warmth of the joint (not necessarily associated with erythema), and muscle atrophy of proximally or distally affected areas. If there is erythema and/or exquisite tenderness with palpation of joints or bones, infection (such as osteomyelitis or septic arthritis), reactive processes (such as rheumatic fever or Henoch–Schönlein purpura), malignancy (such as leukaemia, lymphoma, or neuroblastoma), or trauma should be considered before making the diagnosis of JIA or other rheumatic disease. Table 22.1 lists the differential diagnoses to consider when children present with musculoskeletal pain.

## Pain variables in arthritis

The intensity of pain reported by children and adolescents with JIA is quite variable. Early studies of pain in children with JIA erroneously suggested the condition was less painful than RA (Laaksonen and Laine, 1961). More recent studies in the 1990s, incorporating more developmentally appropriate measures, showed disease-related pain is often underestimated in children with JIA and other rheumatic disorders. In fact, using daily diary methodology, Schanberg and colleagues reported that children with JIA report pain on 70% of days (Schanberg et al., 2003). Most children reported mild to moderate pain, but 25% of children reported pain in the severe range. Interestingly, disease activity predicts less than half of reported pain

variance, and day-to-day variations of pain are influenced by factors such as mood, stress, parental and child coping, and parental pain and health beliefs (Schanberg et al., 2003, 2005).

Although a relationship between increased disease activity and increased pain exists (Malleon et al., 2004; Vandvik and Eckblad, 1990; Varni et al., 1987), research consistently has demonstrated limited predictive value for disease status variables. Across studies, disease status variables typically predict only a small to medium proportion of the variance in children's pain ratings (8–28%; Malleon et al., 2004; Schanberg et al., 1997; Thompson et al., 1987; Vandvik and Eckblad, 1990). Therefore, it is important to delineate other influential factors in the pain experience of children with JIA.

The most highly predictive models of pain variance conceptualize pain report as influenced by multiple factors, including disease variables, demographic variables, psychological variables (such as coping and mood), and environmental factors. In a sample of 56 children with chronic arthritis, Ross and colleagues reported that increased child anxiety, increased maternal distress, and increased family harmony were associated with higher child pain ratings averaged over a 1-month time period (Ross et al., 1993). The authors hypothesized that increased family harmony might lend itself to increased responsiveness to children's pain behaviour, serving to reinforce pain behaviour and pain reporting in children.

Demographic variables such as age may influence JIA-related pain, but findings in cross-sectional studies have not been reproducible. Hagglund and Malleon both identified older age as a predictor of pain in their respective cohorts (Hagglund et al., 1995; Malleon et al., 2004), but other investigators have not found this relationship (Ross et al., 1993; Vandvik and Eckblad, 1990).

The role of psychosocial variables such as emotional distress, mood, stress, and pain-coping strategies in children's pain reporting has been studied in many settings. Schanberg and co-workers investigated interrelationships of daily stress, daily mood, and disease expression. Results of multilevel random effects models indicated that day-to-day fluctuations in mood and stressful events were related to daily symptoms in children with polyarticular forms of juvenile chronic arthritis (Schanberg et al., 2000, 2005). Specifically, worse mood and more stressful events predicted increased daily pain, fatigue, and stiffness. These results confirm other studies which indicate that increased psychological distress (e.g. stress, depression, and anxiety) is related to increased pain reporting and poorer functional outcomes, such as decreased participation in school and social activities (Hoff et al., 2006; Margetic et al., 2005; Ross et al., 1993). Hoff and colleagues found that depressive symptoms reported by children with JIA at a baseline evaluation were predictive of reports of pain and functional disability 6 and 12 months later (Hoff et al., 2006).

Children's coping with pain is another influential factor. The use of catastrophizing (i.e. engaging in overly negative thinking about pain) and decreased pain-coping efficacy predict higher pain intensity across several pain measures and more painful body locations, even after controlling for demographic variables and medical status variables (Schanberg et al., 1997). In a laboratory setting, catastrophizing also predicted higher pain intensity, decreased pain tolerance, and increased pain-related discomfort in children with JIA undergoing experimental cold pressor pain (Thastum et al., 1997, 2001). Recent studies by Thastum and colleagues underscore the

**Table 22.1** Differential diagnoses for musculoskeletal pains in children

Category	Diagnosis	Hallmarks
<b>Anatomic or mechanical issues</b>	Avascular necrosis	Pain with weight bearing
	Osteochondroses (e.g. Legg–Calf–Perthes)	Hip pain and limp
	Apophysitis (e.g. Osgood–Schlatter)	Tibial tuberosity pain
	Ligamentous laxity (e.g. patellar dislocation)	Mobile patella with pain
	Benign hypermobility syndrome	Multi-joint hyperextensibility
<b>Trauma</b>	Fracture	Multiple fractures in young children suggest child abuse; growth plate fractures not seen on X-ray
	Sprain, muscular strain	Physically active teens, unusual <4 years of age
	Haemarthrosis (e.g. haemophilia)	Warm, pain with motion, grossly bloody arthrocentesis
<b>Infections</b>	Reactive arthritis	Post-diarrhoeal or genitourinary infections
	Rheumatic fever	Exquisitely tender migratory polyarthritis of large joints
	Lyme disease	Oligo- or polyarthritis is a manifestation of late Lyme infection
	Viral arthritis (e.g. Epstein–Barr virus, cytomegalovirus, parvo B19)	Often with rash and fever
	Infectious osteomyelitis (bacterial, fungal, tuberculosis)	May be associated with sympathetic effusion of adjacent joint
	Septic arthritis	Typically is associated with redness, warmth, pain with motion, elevated inflammatory markers
<b>Malignancy or other tumours</b>	Leukaemia	Severe night pain can be associated with bony point tenderness and complete blood count abnormalities
	Lymphoma	Matted lymph nodes
	Osteoid osteoma	Night-time pain, often alleviated by NSAIDs
	Neuroblastoma	Abdominal mass
<b>Rheumatic diseases</b>	Juvenile idiopathic arthritis	Multiple subgroups based on clinical characteristics
	Systemic lupus erythematosus	Non-erosive polyarthritis
	Henoch–Schönlein purpura	Purpuric rash on legs, buttocks; arthritis of lower extremities
	Dermatomyositis	Bilateral proximal muscle weakness and rash on face, eyelids, and extensor surfaces of joints
	Sarcoidosis	Joints boggy and painless, associated with rash and inflammatory eye disease
<b>Other inflammatory conditions</b>	Arthropathy related to inflammatory bowel disease	Peripheral arthritis reflects gastrointestinal (GI) disease activity versus axial skeletal arthritis which is independent of GI disease
	Auto-inflammatory disorders	Periodic fever syndromes, C1AS mutations
	Chronic recurrent multifocal osteomyelitis (non-infectious)	Multi-focal affecting long bones as well as mandible, spine, and clavicles; bone biopsy needed for diagnosis
	Arthritis from immunodeficiency	Combined variable immunodeficiency
<b>Pain amplification disorders</b>	Complex regional pain syndrome	Type 1 associated with trauma and with diffuse swelling and discoloration of affected limb
	Fibromyalgia	Sleep disturbance, fatigue and tender points
	Benign limb pains of childhood (e.g. growing pains)	Night awakenings with extremity pain relieved by massage or warm packs
<b>Metabolic and endocrinological</b>	Rickets	Flaring at bony metaphyses on X-ray
	Mucopolysaccharidoses	Gaucher or Hurler

impact of cognitive health beliefs on pain in children with JIA (Thastum and Herlin, 2011; Thastum et al., 2005). Results suggested beliefs about control over pain and the ability to function despite the presence of pain influence the development of effective pain-coping strategies, while dysfunctional health beliefs persist over time in patients with high pain.

Finally, parent and family environmental variables are related to pain report of children with JIA. These variables include the nature of family relationships (family harmony or conflict), increased parent psychological distress, parental responses to child pain, and parent and family pain history (Connelly et al., 2010; Iobst et al., 2007; Reid et al., 2005). For example, in a sample of school-aged children with chronic arthritis, Schanberg and colleagues found that a more extensive parent and family history of pain was related to increased child self-reported pain intensity (Schanberg et al., 2001). Moreover, within the context of hierarchical regression analyses, child catastrophizing mediated the relationship. In other words, parent and family pain variables influenced a child's use of catastrophizing as a coping strategy, which in turn influenced child reporting of pain.

## Diagnosis

The diagnosis of chronic inflammatory arthritis is based on clinical examination and history. No laboratory or radiographic studies make the diagnosis of JIA. Duration of symptoms is extremely important as diagnostic criteria for all the chronic arthritides require the presence of objective joint abnormalities on physical examination (either swelling or pain/tenderness with limitation) in the same joint for at least 6 weeks' time. Acute presentations of joint pain and/or swelling caused by infections, injury, or reactive processes are more common than JIA, and often are self-limited, resolving before 6 weeks. The paediatric Gait, Arms, Legs screen (pGALs) is an excellent screening tool for use by non-rheumatologists that includes a focused joint examination for affected areas which incorporates inspection, palpation, and range of motion (Foster et al., 2006).

## Classification

The nomenclature for childhood onset arthritis has evolved through the years. The current classification system was developed by the International League Against Rheumatism (ILAR; Fink, 1995; Petty et al., 1998, 2004) and uses the term juvenile idiopathic arthritis (JIA) instead of juvenile rheumatoid arthritis (American College of Rheumatology classification; Brewer et al., 1972, 1977) or juvenile chronic arthritis (European League Against Rheumatism classification; Wood, 1978). While the different classification systems have similarities, they are not interchangeable. Within the ILAR classification of JIA, there are seven categories corresponding to different onset subtypes based on the first 6 months of presentation, which include: oligoarticular, polyarticular-rheumatoid factor negative, polyarticular-rheumatoid factor positive, psoriatic, enthesitis-related, systemic, and unclassified arthritis. The ILAR criteria were developed to help provide prognostic information for various subtypes of JIA, as well as provide a framework for research; however, the classification scheme is cumbersome and often misused even by paediatric rheumatologists. In addition, large numbers of patients fall into the unclassified category (Berntson et al., 2001; Kunjir et al., 2010; Merino et al., 2001; Petty, 2001; Ravelli et al., 2011).

## Diagnostic studies

Although inflammatory arthritis is typically a clinical diagnosis, laboratory and/or radiographic evaluations can be helpful in classifying the subtype of JIA or determining if arthritis is part of a systemic disorder. A complete blood count with manual differential, erythrocyte sedimentation rate (ESR) and/or C-reactive protein are often performed to assess for generalized inflammation. A comprehensive metabolic panel, including uric acid and lactate dehydrogenase to look for possible increased cellular turnover noted in malignancies, and urinalysis are useful to assess organ damage or involvement. If pain is not localized at a joint but more diffuse, muscle enzymes such as creatine kinase or aldolase as well as vitamin D and thyroid function levels may be helpful. Often, these ancillary studies are useful in identifying other aetiologies of joint or bony pain such as metabolic diseases and malignancies.

The utility of screening autoantibodies varies depending on the context of ordering the test. If joint or musculoskeletal pain is the only complaint without obvious joint pathology such as swelling or pain on movement/tenderness with limitation (arthralgias), then screening tests have little value and cause undue consternation if abnormal (Wong et al., 2012). In the presence of true arthritis, screening for anti-nuclear antibody, rheumatoid factor (especially for polyarticular presentation), anti-citrullinated cyclic peptide, and HLA-B27 is helpful to determine prognosis and risk of eye disease (Anonymous, 1993; Heiligenhaus et al., 2007).

Radiographic studies assess bony abnormalities or joint destruction such as erosions, but often in JIA these diagnostic studies are negative, especially early in the disease course. MRI and ultrasound are newer modalities used in assisting the diagnosis of arthritis by demonstrating effusions, synovial proliferation, early erosions, increased blood flow, and bone marrow oedema from inflammation, but there are issues with regard to normal standards in the growing skeleton. Therefore, imaging studies are best evaluated by an experienced paediatric musculoskeletal radiologist in conjunction with a paediatric rheumatologist.

## Other rheumatic conditions

Systemic lupus erythematosus, juvenile dermatomyositis, and vasculitis can all present with arthritis as a primary manifestation. Joint or muscle pain can be the presenting symptom for these patients. Typically, other signs and symptoms including rash and constitutional symptoms such as malaise, fever, fatigue, or anorexia guide further evaluation. Screening for organ system damage by looking at renal, cardiopulmonary, and neuropsychiatric function can be helpful in making diagnoses of other rheumatic conditions.

## Treatment/management of pain in children with JIA

The biopsychosocial model of pain provides a useful framework from which to approach managing pain in JIA. In addition to aggressively treating the biological basis of disease, a combination of pharmacological and non-pharmacological modalities can be used to manage pain. Reducing disease activity is associated with improved radiographic outcomes, functional capability and reduced symptoms including pain; however, disease control is not

sufficient to eliminate pain and other symptoms. Further goals of treatment in children and adolescents are to alleviate pain, improve or preserve function, and restore normal growth. Unfortunately, no clinical trials in JIA have addressed pain management as a primary endpoint. Even the original studies of non-steroidal anti-inflammatories (NSAIDs) in children with JIA used disease activity outcomes that included pain, rather than pain alone, to prove efficacy (Giannini et al., 1990; Laxer et al., 1988; Nicholls et al., 1982; Steans et al., 1990).

Initial treatment of pain related to inflammatory arthritides is NSAIDs, adding acetaminophen for acutely painful events. Therapy may be escalated based on disease severity, symptom intensity, functional disability or lack of efficacy, to include: corticosteroids (systemic or intra-articular injections); disease modifying antirheumatic drugs (DMARDs) such as methotrexate, sulfasalazine, hydroxychloroquine, or leflunomide; and biological therapies such as TNF $\alpha$  blockers (etanercept, infliximab, adalimumab, golimumab, certolizumab), interleukin-1 blockade (anakinra, rilonacept, canakinumab), B-cell depletion (rituximab), interleukin-6 inhibition (tocilizumab) and T-cell costimulation blockade (abatacept). Recently, studies of early aggressive treatment (Tynjälä et al., 2011; Wallace et al., 2012) have led to development of algorithms and treatment protocols for various subtypes of JIA (Beukelman et al., 2011; DeWitt et al., 2012; Tynjälä et al., 2011; Wallace et al., 2012). Table 22.2 shows the dosing of agents commonly used to treat pain in JIA.

Intra-articular injection of long-acting corticosteroids can be a highly effective means of immediately reducing joint inflammation and pain, especially for monoarticular or oligoarticular JIA, as well as persistently symptomatic joints in polyarticular disease (Wallen and Gillies, 2006). Because of wide ranging and distressing side effects, as well as concerns about obscuring a diagnosis of cancer, the routine use of systemic corticosteroids to reduce pain is discouraged, except in cases of severe systemic JIA following a bone marrow biopsy to rule out cancer, when arthritis is so severe the child will otherwise become bedridden or wheelchair-bound, or for short-term use while starting a new agent or intervention with delayed effect (Connelly and Schanberg, 2006).

As one of the oldest and most potent anti-inflammatory medication available, systemic corticosteroids have historically been used by practitioners to reduce pain in rheumatic disease even without overt evidence of active inflammation. While corticosteroids immediately reduce inflammation and may secondarily decrease pain with substantial symptom relief, corticosteroids unfortunately do not change the long-term course of arthritis and are not remittive agents so the actual benefit is limited. Corticosteroids can also mask the presence of malignancy or other rheumatic disease and should not be used in the absence of a clear diagnosis or without consultation with a paediatric rheumatologist. In addition, chronic use of systemic corticosteroids has many undesired side effects (e.g. growth retardation, osteoporosis, avascular necrosis, cataracts, and immunosuppression), which are especially devastating for children. Nevertheless, 27% of paediatric rheumatologists surveyed about pain treatment in JIA preferentially prescribed systemic corticosteroids over analgesics to treat residual pain in children with arthritis because of discomfort and lack of training in the use of opioid pain medications (Kimura et al., 2006).

## Specific medications

NSAIDs are the mainstay of pain treatment in paediatric patients with rheumatic diseases (Table 22.2) providing rapid and effective analgesia in a variety of well-tolerated oral preparations (liquid, chewable tablets, tablets, capsules). NSAIDs work peripherally inhibiting cyclo-oxygenase (COX), which reduces prostaglandin production and subsequently pain (see also Anderson, Chapter 43, this volume). Analgesia from NSAIDs may be additive to that of opioids and other adjuvant medications. NSAIDs have a ceiling effect (i.e. increased doses have no further benefit). COX-2 selective inhibitors (meloxicam and celecoxib) are approved by the US Federal Drug Administration (FDA) for use in JIA and are effective and safe (Foeldvari et al., 2009; Ruperto et al., 2005), although there is little information regarding long-term cardiovascular risks in children taking either selective or non-selective NSAIDs.

Significant potential adverse effects from NSAIDs and COX-2 inhibitors include gastrointestinal toxicity (dyspepsia, gastritis, ulcers, constipation and diarrhoea), renal toxicity (interstitial nephritis, papillary necrosis, decreased blood flow, hypertension), hepatotoxicity (hepatocellular injury, cholestasis); cardiovascular toxicity has thus far been reported only in adults. Platelet inhibition occurs with most NSAIDs and needs to be considered in patients with a coexisting bleeding diathesis or prior to a surgical procedure. NSAIDs (especially naproxen) have also been associated with pseudoporphyria, which can cause significant scarring (Lang and Finlayson, 1994). Typically, fair-skinned children are at greatest risk for pseudoporphyria with sun exposure. The skin lesions present as small linear scratches in sun-exposed areas such as the face or arms. Sunscreen use is encouraged while on NSAIDs.

*Acetaminophen* is an appropriate analgesic for mild to moderate pain and can be used in combination with NSAIDs. Patients must be cautioned not to take more than the recommended dosage (10–15 mg/kg/dose every 4–6 h, maximum of 4 g in 24 h). Larger doses, especially taken chronically, can cause significant hepatotoxicity and are an important cause of liver failure. It is important to remember that many analgesics contain acetaminophen as well as the principal analgesic (e.g. Percocet® contains acetaminophen in addition to oxycodone) in order to avoid overdosing patients with acetaminophen.

*Opioids* (see also Strassels, Chapter 45, this volume) which act as agonists blocking principally  $\mu$  and less commonly  $\kappa$  receptors in the central nervous system, are gaining acceptance to treat chronic, non-malignant pain in adults and children (Kalso et al., 2004; Slater et al., 2010). However, a recent Cochrane systematic review did not find strong evidence for long-term use in adult RA (Whittle et al., 2011). Opioids may be better tolerated, have more rapid onset of action, and are potentially less toxic than aggressive immunosuppression. Tramadol is a weak opioid that provides fairly effective relief of mild to moderate pain when NSAIDs and acetaminophen have failed. While there is fair evidence of its efficacy in osteoarthritis (Manchikanti et al., 2011), it has not been studied specifically in children with arthritis. Additional choices for acute pain include various oxycodone preparations, and for long-term pain management methadone (which also acts as an antagonist of NMDA receptors) may be useful. Methadone is not well studied in children but several studies suggest dosing only two to three times per day may be effective (Berde et al., 1991; Brown et al., 2004; Shir et al., 1998).

**Table 22.2** Medications used to treat pain in rheumatic diseases

Name	Dosage	Max. dose/day	How supplied
<b>NSAIDs</b>			
Aspirin	60–100 mg/kg/day Divided 3 times/day	20–30 mg/dl level	Chewable tablet, tablet
Ibuprofen	30–40 mg/kg/day Divided 3 times/day	2400 mg	Liquid, chewable tablets, tablets
Naproxen	10–20 mg/kg/day Divided 2 times/day	1000 mg	Liquid, tablet
Indomethacin	2–4 mg/kg/day Divided 2–3 times/day	200 mg	Liquid, capsule, tablet
Meloxicam	0.125–0.25 mg/kg Once daily	7.5 mg	Liquid, tablet
Celecoxib	50 mg/dose (12–25 kg) 100 mg/dose (>25 kg) 200 } 2 times/day mg/dose (>50 kg)	400 mg	Capsule
Tolectin	40 mg/kg/day Divided 3 times/day	1600 mg	Tablet
Etodolac SR	20–30 mg/day (by age) Once daily	1000 mg	Tablet
Nabumetone	30 mg/kg/day Divided 1–2 times/day	2000 mg	Tablet
<b>Analgesics, including opioids</b>			
Acetaminophen	10–15 mg/kg/dose Every 4–6 h	2–4 g	Liquid, chewable tablet, tablet
Hydrocodone	0.15 mg/kg Every 3–6 h	Limited by side effects	Liquid, tablet
Oxycodone	0.005–0.2 mg/kg Every 3–6 h	Limited by side effects	Liquid, capsule, tablet
Tramadol	25–100 mg Every 6–8 h	300 mg	Tablet
Methadone	0.2–0.4 mg/kg Every 6–12 h	Limited by side effects	Liquid, tablet
Hydromorphone	0.03–0.08 mg/kg/dose Every 4 h	Limited by side effects	Liquid, tablet
<b>Other agents</b>			
Gabapentin	8–35 mg/kg/day Divided 3 times/day	3600 mg	Tablet
Amitriptyline	10–30 mg/day At bedtime	75 mg	Tablet
Pregabalin <sup>a</sup>	150–300 mg/day Divided 2 times/day <sup>b</sup>	450 mg	Tablet
Duloxetine <sup>a</sup>	30–60 mg/day Once daily <sup>c</sup>	60 mg	Tablet

<sup>a</sup>Not FDA approved in children <18 years.<sup>b</sup>Trials in children 12–17 have starting dose of 25 mg with slow titration until effect achieved.<sup>c</sup>Trials in children from 13–17, starting dose of 30 mg.

Despite potential benefits, paediatric rheumatologists rarely use opioids to treat JIA-related pain with nearly 60% expressing refusal to use opioids for chronic pain management in a recent survey even though more than 75% of respondents reported caring for patients with significant arthritis-related pain despite adequate medical treatment (Kimura et al., 2006). Side effect concerns such as drowsiness, fatigue, and constipation as well as respiratory depression strongly influenced paediatric rheumatologists' attitudes toward opioid use, but those opposed to opioid use were most concerned about addiction and dependence ( $\chi^2$  5.51,  $p$  = 0.019). Most side effects, including sedation, nausea, and pruritis are reversible and short term. Additional complications such as respiratory distress can be avoided by starting at low dose and titrating to effect. A pre-emptive bowel regimen, including a stool softener and stimulant, can prevent constipation (Connelly and Schanberg, 2006).

*Adjuvant medications* often are useful for managing chronic pain in children with JIA. The most commonly used medication of this type is amitriptyline, a tricyclic antidepressant used in low doses at night for generalized chronic pain associated with sleep disturbance. However, in an N of 1 Bayesian trial in six children with JIA, Huber found low-dose amitriptyline did not improve pain scores (Huber et al., 2007). Selective serotonin re-uptake inhibitors (SSRIs) may be used to treat comorbid mood disorders in children and adolescents with JIA. Given FDA-mandated black box labeling for SSRIs, these medications should only be used with close follow-up and extensive parent education about the increased risk of suicidality. Adding medications that address neuropathic pain has been advocated in adult arthritis (e.g. gabapentin, pregabalin, duloxetine), but there are no published studies looking specifically at their usage to treat chronic pain in JIA or other childhood-onset rheumatic diseases.

### Surgical interventions

The role of surgery in treating pain and disability in children with chronic arthritis is not straight forward; although several studies suggest children experience marked pain reduction after surgery (Dell'Era et al., 2008; Iesaka et al., 2006; Parvizi et al., 2003). Surgical interventions including synovectomy, soft-tissue release, and arthroplasty are generally limited to children with marked functional impairment, severe disabling pain, or deformity. Whenever possible, the age and skeletal maturity of the child should be considered, and surgery should be delayed until growth plate closure. Surgical interventions should be performed in specialized clinics at tertiary centres with awareness of the presence of arthritis in the cervical spine and temporomandibular joints, if intubation is planned. Pharmacological advances in treating children with chronic arthritis have brought into question the role of surgical interventions and likely will be an increasingly rare occurrence in the future.

### Non-pharmacological interventions

The growing acceptance of the biopsychosocial model of pain has prompted the development and study of non-pharmacological interventions for JIA-related pain. Research on non-pharmacological interventions has included programmes for improving physical conditioning and sleep hygiene, massage therapy, and, perhaps most importantly, cognitive behavioural therapy.

*Cognitive-behavioural therapy* (CBT) aims to manage pain by improving self-reliance and facilitating normal activities through the use of coping skills, decreasing cognitive responses to pain, and using behavioural strategies including progressive muscle relaxation, distraction, and guided imagery (see also Logan et al., Chapter 50, this volume). Addressing coping strategies through CBT is integral to pain management in JIA, as pain coping accounts for a large amount of the variance in self-reported pain intensity over and above the effect of disease activity (Sawyer et al., 2004; Schanberg et al., 1997; Thastum et al., 2005). Two published studies demonstrated improvement in self-reported pain ratings of children with chronic arthritis after CBT both immediately after treatment and at 6-month follow-up (Lavigne et al., 1992; Walco et al., 1992). The studies are limited by small sample size, abbreviated scope of the CBT intervention, and the lack of functional outcome variables. Although future studies of CBT are necessary to understand fully its role in treatment of children with JIA, a systematic review of controlled trials of psychological therapy for chronic pain concluded that there is evidence to support the use of CBT to treat headaches and other types of recurrent and chronic pain in children and adolescents (Palermo et al., 2010). The lack of side effects and the generalizability of the skills make CBT an attractive adjunctive intervention.

*Physical therapy and exercise programmes* can help reduce pain in children with arthritis, who tend to be less physically active and more deconditioned than their peers (Takken et al., 2008). Decreased physical activity as a result of disease symptoms leads to decreased aerobic capacity and endurance, decreased exercise time, and decreased peak workload as compared with healthy controls (Giannini and Protas, 1991; Klepper and Giannini, 1994). Klepper et al. studied the effect of an exercise regimen in 25 children with arthritis, showing that improved aerobic conditioning was achieved and was associated with decreased pain, without disease exacerbation (Klepper 1999, 2008). Several other studies have demonstrated decreases in active joint count and disease severity with initiation of a therapeutic exercise programme, as well as decreased pain and improved cardiovascular fitness, but noted difficulty in motivating patients to continue achieving aerobic goals (Singh-Grewal et al., 2006, 2007; Takken et al., 2008). Future studies are necessary to delineate the most appropriate exercise for children with arthritis.

Improving *sleep quality* often is overlooked in the treatment of pain. One study described frequent night waking, parasomnias, sleep anxiety, sleep-disordered breathing, and daytime fatigue in children with arthritis compared with controls and disturbed sleep was associated with increased pain (Bloom et al., 2002). Bromberg and colleagues found that self-reported nightly sleep quality was highly predictive of pain the following day, with better mood attenuating the effect (Bromberg et al., 2012). Thus, even simple measures to improve sleep, including use of a supportive but soft mattress and sleeping in warm pyjamas (e.g. sweat clothes), should be recommended to children with JIA. Physical therapists also can suggest sleep positions that maximize level of comfort depending on the unique combination of active joints. Relaxation techniques, such as progressive muscle relaxation or guided imagery taught within the context of cognitive behavioural therapy, also can be useful in improving sleep hygiene.

*Other interventions*, including integrative approaches (see Zeltzer, Chapter 60, this volume) to improve pain in children with JIA have not been well studied; however, limited research includes studies of the use of massage and orthotics in children with JIA and several interventions in adult RA. Field and colleagues evaluated the effectiveness of massage in decreasing pain in a sample of 20 children with mild to moderate arthritis (Field et al., 1997). Children were randomly assigned to either a massage therapy or relaxation techniques control group. Immediately after treatment, children who received massage had lower levels of anxiety and decreased salivary cortisol levels. They also reported less present pain, less pain during the past week, and fewer painful locations than children in the control condition. A controlled trial of 40 children investigating the effectiveness of custom orthotics showed significant improvements in pain, ambulation speed, and self-related functionality and activity, when compared to children using over-the-counter inserts and supportive athletic shoes (Powell et al., 2005).

An evidence based review of non-pharmacological treatments for adults with rheumatoid arthritis found that aerobic physical exercise, sports, and muscle-strengthening exercises demonstrated positive benefit in pain and health related quality of life; however, there was little evidence that dietary measures, nutritional supplements and elimination diets were effective (Gossec et al., 2006). Further controlled studies on these and other non-pharmacological interventions are required before reaching conclusions relating to the effectiveness of these approaches in children with JIA-related pain.

## Outcomes

More comprehensive assessment and tracking of pain in children with rheumatic conditions are needed upon which to base future treatment considerations. Currently, there is no generally accepted, standardized method of assessing pain for children with rheumatic conditions and pain improvement is not considered independently in either pharmaceutical or investigator-initiated medication efficacy trials, despite a call from the international paediatric pain community to perform more comprehensive pain assessments in children participating in clinical trials (McGrath et al., 2008). A Childhood Arthritis and Rheumatology Research Alliance (CARRA) initiative has sought to formalize pain assessment as part of the routine evaluation of children and adolescents presenting to paediatric rheumatology clinics (Stinson et al., 2012). Additionally, more in depth understanding of the context of pain in JIA is needed to guide development of more effective interventions. Symptom tracking using electronic diaries or other mobile technologies can reveal the ecological momentary impact of pain in JIA, demonstrating hourly as well as daily variability not apparent in cross sectional pain assessments during routine clinic visits (Connelly et al., 2007; Schanberg et al., 2003; Stinson et al., 2006, 2008).

Extremely important in any assessment of pain is gathering information directly from children themselves as studies show a lack of concordance between provider, parent, and patient perceptions of pain, especially as children get older and depression or other psychological distress is more common (Garcia-Munitis et al., 2006;

Lal et al., 2011; Palermo et al., 2004). Tong and colleagues' recent systematic review of qualitative studies about the experiences of children with JIA identified six major themes: aversion to being different, striving for normality, stigma and understanding, suspension in uncertainty, managing treatment, and desire for knowledge (Tong et al., 2012). Of note, pain from JIA, its impact and management were pervasive within all themes and the author's conclusions reinforce the concepts and framework of the biopsychosocial pain model.

Chronic recurrent pain in children, which likely includes those with JIA, is known to have negative short-term impact including poorer social and peer relationships, missed school and decreased functionality, and emotional and psychological distress (Connelly et al., 2012; Eccleston and Crombez, 2007; Haverman et al., 2012; Palermo, 2000; Roth-Isigkeit et al., 2005). Without properly addressing pain as a standard part of JIA treatment, long-term disability and increased medical expenditures may result (Arkela-Kautiainen et al., 2006; Foster et al., 2003). Understanding relationships between pain, school attendance, sleep, stress, emotion regulation, and mood will guide development of interventions designed to enhance the functionality and productive coping of children and adolescents with JIA.

To improve routine care of children with JIA, pain assessment and control are included in proposed standards for health care delivery quality measurements (Lovell et al., 2011). Consensus assessment and treatment plans addressing pain in children with JIA are being developed through CARRA and will provide recommendations regarding use of various treatment modalities to manage the multifactorial nature of pain in rheumatic conditions. Additionally, validation and standardization of outcome measurements for the assessment of paediatric rheumatic conditions, which includes pain intensity assessment, are being addressed through worldwide efforts through organizations such as Paediatric Rheumatology INternational Trials Organisation (PRINTO) and Pediatric Rheumatology Collaborative Study Group (PRCSG). With the advent of newer agents introduced earlier in the disease course to quickly limit inflammation, new studies are needed to investigate if shifts in the treatment paradigm result in fewer pain complaints and less pain related functional limitation. Consensus derived algorithms will standardize assessment and treatment of JIA-related pain in clinical settings. Through comparative effectiveness research studies using the CARRA network, we can evaluate the best modalities to approach pain.

## Conclusion

Pain is common in children with inflammatory arthritis despite aggressive treatment of JIA with contemporary medications. Pain is an important, but often neglected, aspect of care for children with arthritis, negatively impacting well-being and function. Further research is needed to prospectively identify patients and families early in the course of disease who would benefit from additional support to optimize pain management and limit distress. In addition, future clinical trials should assess the impact of study interventions on pain as a primary endpoint, assessed independently from other response variables.

### Case example

A 15-year-old adolescent female presents for evaluation of diffuse musculoskeletal pain, which has been ongoing for 2 years. In the past, she was able to cope with the pain and keep playing basketball, her favourite sport. Over the past 6 months, she stopped playing basketball due to swollen knees and lower back pain. Every morning she is stiff for 2 h. Physical exam shows arthritis of both knees, but also exquisite tenderness at bilateral sacroiliac joints with poor flexion of the lumbar spine. She also has enthesitis (tenderness at the bony insertion points of tendons and ligaments) at bilateral Achilles tendons, greater trochanteric heads, tibial tuberosities, and anterior superior iliac crests (see Figure 22.2). Laboratory evaluation includes normal blood counts with elevated ESR of 50. HLA B27 is positive but antinuclear antibody, rheumatoid factor, and anti-citrullinated cyclic peptide are negative. MRI and plain films reveal erosions at her sacroiliac joints. Her primary care provider has started ibuprofen 600 mg three times daily. Since starting the medication, she is moving better with morning stiffness lasting only an hour. Her knee swelling is unchanged.

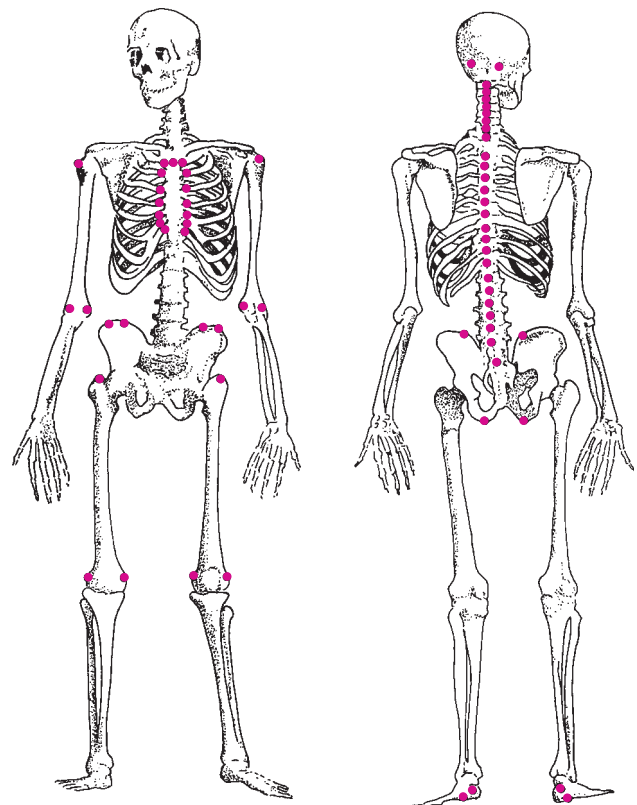

Given the clinical picture, she was diagnosed with enthesitis-related juvenile idiopathic arthritis, also known as a seronegative spondyloarthritis, by a paediatric rheumatologist. Because of the severity of joint findings on imaging, she immediately was started on a TNF- $\alpha$  blocker and underwent intra-articular joint injections for her knees. With initiation of treatment, her inflammatory lab markers normalized, her knee swelling fully resolved and she resumed most normal daily activities. Unfortunately in follow-up, she still complained of back pain, which she now characterized as extending up her entire back into her neck, shoulder blades and including her lower back. She is worried that the newly diagnosed arthritis is worsening since her pain has changed, and is now sharper, more stabbing in nature and seems to affect more body parts including hips, knees, shoulders and elbows. She also is fatigued, often missing school. A short course of oral prednisone does not provide relief or improvement in her symptoms.

On further history, she endorses non-restorative sleep and multiple psychosocial and emotional stressors, including recently breaking up with her boyfriend. Previously, she was physically active but has not engaged in aerobic activity since onset of the knee arthritis. She expresses desperation to get to back to feeling normal. Re-examination shows no obvious joint abnormalities but she has diffuse musculoskeletal tenderness at her gluteal insertions and other tender points. To address the current concerns, she was started on low-dose amitriptyline to help with sleep and provided a regimented physical therapy programme including range of motion and core strengthening exercises, as well as a conditioning programme to work on aerobic capacity for eventual resumption of her previous physical activities. Additionally, she is referred to a therapist for counselling regarding pain coping strategies.

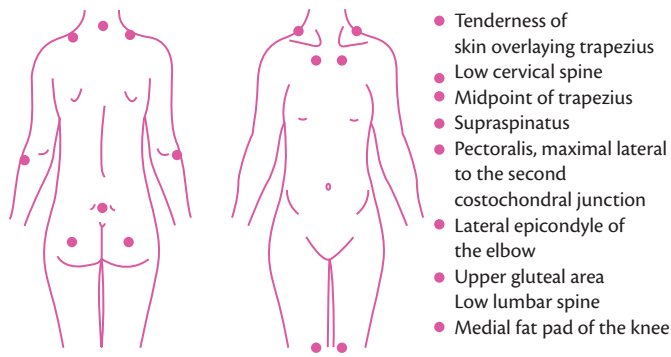

In the setting of enthesitis-related JIA (also known as juvenile spondyloarthritis), fibromyalgia overlay can occur, especially in females, making the diagnosis and assessment of current health status especially challenging (Aloush et al., 2007; Fitzcharles and Boulos, 2003). Characteristically, this form of JIA

is more frequent in males than females and is not associated with autoantibodies such as rheumatoid factor or antinuclear antibodies. Because arthritis may be limited to the axial skeleton, overt joint abnormalities may not be present. Enthesial tenderness can overlap or be in similar locations as fibromyalgia tender points (Figure 22.3), for example, as noted in the gluteal region and hip girdle (Fitzcharles and Esdaile, 1997). TNF- $\alpha$  blockade (such as etanercept, infliximab, golimumab, or adalimumab) treats the inflammatory component of this form of JIA extremely well, even helping heal destructive changes noted in the axial skeleton.

Secondary fibromyalgia is common in adult patients with rheumatic conditions, but also occurs in children and adolescents. Treatment of pain should incorporate a biopsychosocial model addressing all elements that may be contributing to her current health status: anti-inflammatories and immune modulators for inflammation, physical exercise for fatigue and functional limitations, and counselling to improve pain coping and address psychological and emotional confounders. For this teen, initiation of amitriptyline to improve sleep quality, graduated aerobic exercise in addition to adjunctive treatment with a TENS unit or massage therapy, as well as cognitive behavioural therapy will help manage residual pain. Escalation of arthritis treatment such as using courses of oral or parenteral corticosteroids do not treat the central pain processing changes underlying diffuse persistent pain or impact factors moderating pain in the case of this teen.

## CHAPTER 23

---

# Chronic pain syndromes in childhood: one trunk, many branches

Neil L. Schechter

### Summary

Although this volume is replete with detailed discussions about specific pain problems, the focus of this chapter is on a discussion of the commonalities in aetiology, associated symptoms, and treatment of many of the frequent chronic pain problems. We will explore in brief the data that demonstrates the co-occurrence of many of the common chronic pain problems in children and the epidemiological similarities that exist between affected individuals. Then we will review the concept of central sensitization and the physiological evidence that supports its presence in many of the functional pain problems. We will briefly review some of the symptoms associated with these entities (orthostatic intolerance, sleep disturbance, depression, anxiety, hypermobility, family distress). Finally, we will discuss briefly a general approach to these problems emphasizing the collection of specific information in the history and physical examination, the critically important presentation of the formulation to the family, and the treatment modalities that appear to be effective for many of these conditions. In-depth discussion of each of these pain problems is available in chapters specifically designated to review them in detail.

### Introduction

In this chapter, we will highlight relevant issues around the frequent co-occurrence of common chronic pains. This overlap may easily escape the notice of busy specialists who tend to focus on the specific symptoms most relevant to their discipline. For example, it would not be unusual for a child who is being evaluated for persistent abdominal pain by a gastroenterologist to simultaneously be experiencing headache or widespread musculoskeletal pain. Because these symptoms are not the focus or expertise of the gastroenterologist, he or she may ignore these additional symptoms assuming that they will be addressed by others. As a result, the frequency with which these pains co-occur and the similarities in their aetiology and treatment may not be fully appreciated. By the end of this chapter, we hope that the reader will appreciate the importance of recognizing the common elements that bind these

entities together and the importance of their simultaneous evaluation and treatment. Such an approach will hopefully reduce the burden of unnecessary investigation and treatment in these children who are often already overwhelmed by the collective efforts of the medical community.

### Epidemiology of chronic pain in children

There has been long-standing recognition that children and adolescents experience chronic pain and that it is a relatively common experience for them. In a large community sample, Perquin et al. (2000) reported an incidence of chronic pain (defined as recurrent or continuous pain for more than 3 months) of 25% with headache, abdominal pain, and limb pain the most common presentations. There have been multiple other large-scale surveys which report a similar incidence.

Additionally, the co-occurrence of chronic pain problems has been recognized for many years in the adult literature. Table 23.1 presents selected data adapted from a comprehensive review of this subject by Yunus (2007a). He summarizes the data which demonstrates the likelihood of having a second chronic pain syndrome in individuals who have at least one. For example, he reports that the prevalence of irritable bowel syndrome is 45% in individuals with fibromyalgia (with a range of 32–70% depending on the study). Yunus identified the co-occurrence of fibromyalgia, chronic fatigue syndrome, irritable bowel syndrome, tension and migraine headaches, temporomandibular disorders, primary dysmenorrhoeal pain, post-traumatic stress disorder, and multiple chemical sensitivities. As is evident from this chart of studies on adults, there is frequent overlap among these entities which Yunus calls central sensitivity syndromes based on his hypothesis of their aetiology.

The overlap of these syndromes in the paediatric population is a more recent discovery. Although Zuckerman et al. (1987) noted the frequent coexistence (22%) of headache and stomach aches in preschool children in England when surveying the community for the incidence of these pain problems, the significance of this overlap in children was not a focus of research in the paediatric literature until 1997, when Krstjansdottir (1997) studied this phenomenon

**Table 23.1** Associations among central sensitivity syndromes (CSS)

Condition	Mean prevalence (%) of another CSS in patients with this condition (range of %)	Total no. of studies	Total no. patients
FMS	CFS 39 (22–74)	6	214
	IBS 45 (32–70)	17	1776
	Migraine 38 (22–49)	3	183
	UHA 50 (35–56)	5	558
	TTH 42 (22–60)	5	889
CFS	FMS 48 (16–80)	2	57
	IBS 36	1	25
IBS	FMS 36 (28–65)	5	179
	CFS 14	1	200
	UHA 42 (31–50)	3	297
Migraine	CFS 51	1	63

FMS = fibromyalgia syndrome; IBS = irritable bowel syndrome; TTH = tension headache; UHA = unspecified headache.

Yunus, Fibromyalgia and overlapping disorders: the unifying concept of central sensitivity syndromes, pp. 339–356, Copyright © 2007, with permission from Elsevier, <http://www.sciencedirect.com/science/journal/00490172>.

directly. She reported that over a 3-month period, 21% of children who had one pain had at least one other. Subsequently, other investigators found a co-occurrence rate that ranged from a low of 5% (Larsson and Sund, 2007) to a high of 50% (Kroner-Herwig et al., 2011) depending on definitions of chronic pain. Fichtel and Larsson (2002) found that almost 15% of their Scandinavian sample of children with chronic pain had four or more pain sites.

## Shared biological and clinical features

The recognition that multiple pain sites are common in individuals who have chronic pain has prompted a more in-depth look for similarities between these entities. The fact of their frequent co-occurrence has significant research implications as it requires an explanatory model that is broader than focus on a specific end organ (stomach, back, head, etc.). It is not only the frequency of overlap of these entities that is noteworthy, however, but also the co-occurrence of many other associated features. These include female predominance, association with psychological disorders, school and sleep disruption, frequent fatigue and loss of mental clarity. Additionally, many of the same centrally acting non-specific treatments (exercise, stress reduction, acupuncture, neuromodulating drugs such as antidepressants and anticonvulsants) are effective for these all of these syndromes. These shared characteristics provide further support for the linkage of these entities and add to the critical importance of a multidisciplinary approach which allows the insights of researchers who had been narrowly exploring one type of pain to influence the thinking of those exploring other pain problems. In this section, we will review the evidence that supports the existence of the numerous commonalities among these entities. Because much of the work stems from adult research, we will use the schema devised by Mayer and Bushnell (2009) in the final section of their seminal volume on functional pain syndromes where they attempt to synthesize what we have learned about the inter-relationship of these common problems in adults and add paediatric data where it is available.

## Evidence for shared biological mechanisms

Although the data is still emerging, it appears from multiple streams of evidence that many of the functional pain syndromes are associated with abnormalities of nociceptive processing which may account for the fact that individuals with these conditions often experience severe pain without evidence of structural pathology or other physiological derangement. This may result from, depending on the condition and situation, enhanced neurotransmission stemming from hyperarousal of central neurons (central sensitization) (Geisser et al., 2008; Giesecke et al., 2004; Woolf, 2001), autonomic nervous system dysfunction (Janig, 2009), hypothalamic–pituitary–adrenal axis dysfunction (Chang et al., 2009), and/or from dysfunction of descending pain modulatory abilities (Johannesson et al., 2007; Lautenbacher and Rollman, 1997). Even though the mechanistic details require more research and may vary from individual to individual, there is a robust literature which suggests that individuals with functional pain syndromes often have an altered response to clinical and experimental pain exemplified by increased spontaneous firing, decreased threshold, increased response amplitude, expanded receptive field. This is evident on both oral reports of increased pain in clinical situations and on laboratory induced pain as well as on functional magnetic resonance imaging evaluations which suggest an altered pain response in individuals with chronic pain as compared to controls.

This recognition has led a number of investigators to conclude that at their core, many of these entities have a similar aetiology—a hypersensitivity to noxious and non-noxious stimuli typically known as central sensitization (Woolf, 2011) which is multifactorial in origin. In fact, Yunus (2007a, 2008) has recently clustered a number of these entities together under the rubric of ‘central sensitivity disorders’ implying the centrality of central sensitization in their aetiology. He identified research that demonstrated an altered response to pressure, heat, cold, and auditory sensations in adults with migraine, fibromyalgia, and irritable bowel syndrome. Similarly, Von Baeyer and Champion (2011) conclude that these

problems are all manifestations of an underlying pain vulnerability which stems from multiple sources but yields similar outcomes.

The origins for this increased susceptibility to pain are quite complex and not fully understood and likely vary from individual to individual. Mayer and Bushnell (2009) and Yunus (2007b) have suggested that this alteration may emerge from multiple mechanisms, both biological and social. These may include genetic predisposition, anxiety or depression, increased psychosocial stressors, early life adversity, infections, and/or inflammation. Microtrauma such as that stemming from hypermobility or overuse may also play a role. These factors may impact on the central nervous system and cause the hyperexcitability that is called central sensitization which they feel is the core biological link and final common pathway to the creation of functional pain disorders. Other models suggest while acknowledging the centrality of central sensitization that psychological factors exert their influence independently and not necessarily through a hyperexcited central neurons.

As should be evident from the preceding discussion, if one assumes that functional pain disorders emerge from a composite of biological vulnerabilities and psychosocial factors which jointly create abnormalities of pain processing or the misperception of those signals, then the notion that pain can be categorized as strictly physical or psychological is highly outdated and in fact destructive. Unfortunately, however, many families may become frustrated by the traditional approach to unexplained pain—extensive laboratory investigation and imaging which if negative results in referral to a mental health professional. It is essential that the child and family understand that declaring the pain syndrome to be functional does not at all imply psychogenesis. The pain itself is the disease.

### Shared clinical features

Besides abnormalities of nociceptive processing, there are a number of other clinical and epidemiological characteristics of functional pain syndromes that link them together—they occur predominantly in females, there is often a family history of pain problems, there is an association with early life trauma, and they frequently occur in individuals with specific personality types and mental health disorders. Additionally, they often co-occur with other clinical conditions in which there is autonomic dysregulation such as postural orthostatic tachycardia syndrome. Finally, they all seem to respond, at least somewhat, to centrally acting interventions such as anticonvulsants and antidepressants, exercise, acupuncture, stress management, and cognitive-behavioural therapy.

### Greater prevalence in girls and women

For reasons that are not entirely clear at this time, adolescent girls and women are much more likely to experience chronic pain than boys and men. In community-based studies, girls are twice as likely as boys to report chronic pain (Perquin et al., 2001). A similar finding is reported in analyses of paediatric chronic pain attendees where in one study, 73% were female (Vetter, 2008). The numbers vary depending on the study but the incidence of abdominal pain, fibromyalgia, and migraine headache is much higher in girls than in boys. Although there is much speculation as to the origin of these differences, the finding that girls report more chronic pain than boys is robust and consistent. There is certainly precedent for sex differences in neurological phenomena. For example, the incidence of attention deficit-hyperactivity disorder, enuresis, and learning disabilities is much higher in boys than girls.

### Family history

There is strong evidence that chronic pain problems tend to run in families. This is most likely due to a number of factors including the genetics of nociception, genetic inheritance of painful conditions, and parental modelling of pain behaviour.

Studies have attempted to evaluate the relative contributions of genetics to variations in pain sensitivity, in both animals and humans (Foulkes and Wood, 2008). For example, Mogil and colleagues compared the pain thresholds within and between 11 inbred laboratory mouse strains using multiple laboratory-induced pain modalities and identified significant genetic contributions to nociception and a variety of candidate genes (Mogil et al., 1999).

In addition to experimentally induced pain, several studies have investigated the genetic contribution to differences in severity of and susceptibility to certain chronic pain conditions. A recent study by Kato and colleagues which included 15,950 pairs of twins, found a genetic contribution of about 50% to the likelihood of developing fibromyalgia (Kato et al., 2006). The inheritance of other chronic pain problems has been studied. Migraines (with and without aura) all have a substantial risk of familial recurrence. Concordance rates for migraine are consistently higher among monozygotic than dizygotic twins (Montagna, 2008). Thirty-three per cent of individuals with irritable bowel syndrome have a family history (Whorwell et al., 1986). There is similar data for other central sensitivity syndromes.

Additionally, a number of environmental characteristics may play an important role. Parental modelling of pain behaviour has been demonstrated to increase pain behaviour in their children. Parents with pain are more likely to have children with pain and children are more likely to have pain sites that are similar to their parents (Evans et al., 2007). Parents' interactions with their children may have a role in influencing the likelihood that the pain will affect the child's functioning (Goodman and McGrath, 2003). The relative contribution of genetics, modelling, and parental response to the pain experience probably varies from child to child but it is clear that chronic pain aggregates in families. Schanberg and colleagues (2001) reviewed the family history of 100 patients seen in a paediatric rheumatology clinic and found that 90% of parents reported at least one chronic pain condition, typically lower back pain, shoulder/neck pain, and migraine headache. On average, parents reported a history of 3.5 chronic pain conditions. Ninety-three per cent of parents reported at least one relative with chronic pain in their immediate family. It is critical therefore that a detailed family history be obtained to further our understanding of the factors contributing to the child's chronic pain.

### History of adverse life events

There is an emerging literature on the impact of early life events on the development of nociceptive pathways and on the development of chronic pain subsequently. The strongest work in this field comes from the animal literature in which rodents are subjected to a variety of noxious experiences and the impact of those on subsequent pain responsiveness is assessed. Rat pups subjected to daily foot shocks during their equivalent developmental phase to the human neonatal period demonstrated long-term effects on sensitivity to pain and on their response to morphine subsequently (Shimada et al., 1990). Likewise, rat pups subjected to inflammatory pain, skin wounding, and visceral stimulation such as colorectal distension demonstrated increased visceral sensitivity and other

changes in sensory pathways long after the stimulation had ceased (Al-Chaer et al., 2000).

More subtle adverse experiences in animals have also been shown to impact pain sensitivity and pain thresholds as well. In a series of studies, rat pups subjected to maternal separation experienced both a dampening of their stress response as evidenced by decreased stress hormone output and a heightened sensitivity, depending on the timing of the separation. Interestingly, in one study, pregnant rats were subjected to inescapable stress during the last week of pregnancy. Stress appeared to cause cognitive delays, anxiety, and hypersensitivity of the adrenal stress response in their offspring. Together, this work suggests that noxious events early on, both subtle and pronounced, can impact on the subsequent pain experience of rodents (Al-Chaer and Weaver, 2009).

The literature in humans on the relationship of early adverse life events and pain is more tenuous although suggestive of a similar relationship to that found in animals. For example, Hermann and colleagues (2006) compared the responses on quantitative nerve testing between a group of 9- to 14-year-old children who had prolonged time in the neonatal intensive care unit with those who did not. They found that consistent with animal findings, pain experiences in the neonatal period were associated with alterations in thermal pain responsivity in school-aged children who had been born preterm suggesting that those experiences created measurable differences in nociception many years after they had occurred.

Additional literature to support the long term impact of early life events on pain emerges from the abuse literature. Chartier et al. (2007) identified the fact that individuals who had been abused as children had statistically more physical complaints than those who were not abused. In a community sample of women, individuals with chronic pain were far more likely to have an abuse history than those who did not have chronic pain (Walsh et al., 2007). Together, this animal and human research strongly suggests that early life circumstances can alter nociception.

### Temperament/personality

A number of studies have investigated the relationship of temperament, generally assumed to be the innate biological underpinning of personality, in children and response to painful procedures. Schechter et al. (1991) in a prospective study identified that children with a 'difficult temperament cluster' were more reactive to immunization than children other children. Chen et al. (2000) constructed a pain-sensitive temperament cluster and found that children with acute lymphocytic leukaemia who rated more highly on that scale were more likely to report a higher level of distress during lumbar punctures than those who did not.

The literature on the relation of personality and chronic pain is a bit more complex and far beyond the scope of this chapter but it is likely that personality may have a role in the development of chronic pain and certainly on one's ability to cope with it.

### Comorbidity with disorders of mood and affect

Research on comorbid psychiatric disorders in chronic pain reveals that patients with mental health disorders are significantly over-represented in chronic pain clinics (Bair et al., 2008; Lynch et al., 2006; Varni et al., 1996; White and Farrell, 2006). The relationship between psychological factors and both acute and chronic pain is extensively explored throughout this volume. There is clearly the need for population-based prospective studies to examine this issue but few could disagree with the frequent co-occurrence of mental

health concerns and pain. Regardless, whether anxiety and depression stem from having chronic pain and/or are precursors to it is less relevant to this discussion than the fact that these disorders require treatment as part of a comprehensive approach to pain.

### Response to centrally acting, non-specific therapies

Another intriguing overlap between these disorders is their response to centrally acting and often non-specific treatments. It is clear, for example, that centrally acting drugs such as selective serotonin re-uptake inhibitors and serotonin-noradrenaline reuptake inhibitors, tricyclic antidepressants such as amitriptyline or nortriptyline, and anticonvulsants such as gabapentin or pregabalin seem to decrease chronic pain symptoms in most functional pain syndromes. Additionally, other non-pharmacological approaches such as exercise, stress reduction, cognitive-behavioural strategies, and acupuncture all have demonstrated efficacy in diminishing pain in individuals with many of these pain disorders.

There are numerous studies that support the efficacy of non-specific treatments in chronic pain. For example, amitriptyline appears effective at reducing pain in functional abdominal pain, tension and migraine headaches, and in fibromyalgia (Goldenberg et al., 1996; Hershey et al., 2000; Rajagopalani et al., 1998). Likewise, there is evidence that both exercise and acupuncture is also effective for all three of these entities (Drossman, 1999; Köseoglu et al., 2003; Martin et al., 2006; Meiworm et al., 2000; Melchart et al., 1999; Takahashi, 2006). Finally, studies have identified that cognitive-behavioural therapies and stress reduction techniques diminish pain in chronic pain syndromes as well (Drossman, 1993; Nelson, 2006; Thorn et al., 2007). The fact that similar interventions are effective for many different types of chronic pain in children adds further credence to the notion that they are fundamentally linked at some level.

### Orthostatic intolerance

It has become increasingly clear that chronic pain is often associated with autonomic dysregulation. This is often manifested through orthostatic intolerance, the prime example which is postural orthostatic tachycardia syndrome (POTS) which is often present in individuals with chronic pain. POTS typically occurs following illness or injury. Ohja et al. (2011) identified the fact that in patients with POTS, 75% had gastrointestinal pain, 40% had headache, and 98% had a sleep disorder. Kitzberger et al. (2011) examined the relationship between chronic pain, autonomic function, physical disability, and psychological function and found that heart rate changes of greater than 30 beats per minute associated with positional change (the traditional adult POTS criteria) in patients with chronic pain were associated with higher levels of disability, depression, and anxiety. Although there is some debate as to whether a 30-beat increase is an appropriate threshold for children (Singer et al., 2012), evaluating the child for orthostatic intolerance should be part of the physical examination of any child with chronic pain.

### Hypermobility

There are a number of studies which suggest that joint hypermobility is associated with chronic fatigue and fibromyalgia (Castori et al., 2011; Voermans et al., 2010). Rozen et al. (2006) has suggested that cervical hypermobility is more frequent in individuals with headache disorders than in the general population. Sacheti et al. (1997) reported on the high incidence of abdominal pain in individuals with Ehlers-Danlos, hypermobile type. The mechanism may stem

from central sensitization due to a continuous afferent stimulation from frequent microtrauma due to subluxations or dislocations or from other factors, but hypermobility is often identified in individuals with chronic pain.

### **Sleep dysfunction**

Roth-Isigkeit et al. (2005) reported that the incidence of sleep disturbance in a cadre of children with various chronic pains was 53%. Most clinicians who work with children with all types of persistent pain would agree that issues around sleep are a common occurrence in their patients. Clearly, pain and sleep are inversely related—the more pain, the less sleep; the less sleep, the more pain. It appears that poor sleep increases pain perception and reduces one's ability to cope with pain thus increasing pain and further decreasing sleep. Sleep difficulties may present as delays in sleep initiation, multiple night awakenings, non-restorative sleep, or early morning awakening. Palermo and Fonareva (2006) have reviewed this topic and suggest that although the adult literature is replete with studies which identify a relationship between chronic pain and poor sleep, there is a paucity of such studies in children. The few studies that have attempted to use theoretically objective measures to assess sleep (polysomnography and actigraphy) have yielded somewhat inconclusive results although the preponderance of evidence suggests that like in adults, sleep is often impaired in individuals with chronic pain and it should be addressed as part of comprehensive approach.

### **Impact on school and family life**

In addition to their similar biological and clinical features, these syndromes have a similar impact on children and their families. All chronic pain problems interfere with the child's schooling and enjoyment of daily life. They have a direct impact on the family as well, causing both financial and emotional distress.

### **Impact on school**

It is intuitive that chronic pain would have an impact on school performance and numerous studies validate this assumption. The frequency of school absence has been formally studied in many of the functional pain disorders and is clearly increased compared to the non-pain population (Sato et al., 2007). In fact, rates of school absence for children with chronic pain often exceed those with other chronic health conditions (Palmero, 2000). For a small group of children, that impact is so pronounced that they formally withdraw from school. Vetter found that 12% of children with a variety of chronic pain problems are home schooled and that those who are not miss on average 3 days of school per month (Vetter, 2008). Logan and colleagues (2008) reviewed the school performance of over 200 children attending a chronic pain clinic. They examined data on the school performance using a variety of sources including child and parent reports and school records and found surprising concordance among informants. They found that many adolescents with chronic pain miss a significant amount of school, experience a decline in grades, and perceive pain to interfere with their school success. Why do some children with chronic pain attend school and others with similar conditions do not? Obviously the answer is complex and a number of factors are probably at play. Breuner et al. (2004) studied almost 300 children with headache and found that children with high absences (greater than 2 days in the last

6 months for pain) differed from the low absence group (less than 2 days) primarily on two variables. The high-absence group was more likely to have depressed mood and a lower academic performance than the low-absence group. School avoidance may be a significant contributory factor in a subgroup of these children.

It is clear, therefore, that school absence is a critical issue in the rehabilitation of children with chronic pain. The more school one misses, the greater the anxiety that surrounds school re-entry which may potentiate the pain experience which will promote further school absence. This cycle must be addressed as part of a comprehensive approach to chronic pain.

### **Family distress**

The persistence of pain in a child, regardless of its aetiology, often takes a significant toll on the family at multiple levels. Watching your child suffer with pain that you cannot ameliorate is agonizing for many parents and frequently leads to emotional distress. In a study by Eccleston et al. (2004), 40% of parents of children with chronic pain had depressive symptoms and 60% had a high level of general anxiety; 66% of parents had high scores on parenting stress indices. Feelings of guilt and inadequacy are frequent and parental conflict commonly increases.

Adding to family distress are the financial burdens typically associated with paediatric chronic pain. Sleed et al. (2005) examined the economic impact of chronic pain in an adolescent rheumatology clinic in the UK. She found that the cost of adolescent chronic pain averaged about £8000 —approximately £14 000 for those with non-rheumatological disorders and £4500 for those with rheumatic disease. In addition to the direct costs of medical care (diagnostic testing, medical visits, hospitalizations, medications), the burden of which will vary depending on the specific health care system, there are many indirect costs to families. She found that in the 52 families of children who had chronic pain that she evaluated, family members missed on average 78 work days per year (20% of the working year). In addition to time off from work, there were expenses associated with lost productivity, transportation, additional childcare expenses, non-prescription medications, special foods, plus a number of other out of pocket expenses which all add to the financial pressures on families. Coupled with the emotional stressors, these create a great weight on families who must grapple with these complexities.

### **Treatment implications**

As should be clear from the previous discussion, the purpose of this chapter is to highlight the commonalities that exist among functional pain problems which may not be evident if one focuses solely on individual pain sites. Importantly, many of the similarities in aetiology and impact between these entities have treatment implications. In fact, a number of the interventions that may be recommended to address the abdominal pain in Constance, the young woman in the case example presented in this chapter may be equally efficacious for her headache and musculoskeletal pain as well.

The first goal of treatment is to evaluate the patient for red flags that would imply traditional organic disease. Even if these are identified, however, symptom treatment is still critical as merely treating the disease does not necessarily immediately eliminate distressing symptoms. The following discussion, however, assumes that organic disease is not present or has been well controlled yet pain persists.

## Feedback to families

### Goals of the feedback session

The feedback session in which the nature of the functional pain problem that the child is experiencing is explained is critical to the successful rehabilitation of it. The discussion is remarkably similar regardless of the specific site of the pain or the number of sites involved. At its conclusion, the family should be reassured that the doctor understands the child's problem, that he or she does not believe it is solely in their child's head, and that all are comfortable with a functional diagnosis with minimal subsequent testing necessary. Lindley identified the factors associated with limited improvement after one year in children with functional abdominal pain and reported that acceptance of the diagnosis by the child and family was essential to recovery (Lindley et al., 2005). The feedback session should also emphasize that improvement will be gradual, and that both parent and child participation in the process are essential.

### Setting the stage

It is not uncommon for children with functional pain syndromes, especially those who have multiple pain sites, to have seen a number of clinicians and to have had extensive imaging and laboratory investigation. Because functional problems often have no confirmatory tests, if no traditional organic explanation is uncovered at the end of the investigative journey, families will sometimes urge clinicians to order additional tests in the hope that the answer lies in the results of the next investigation. It is therefore important to present a functional pain diagnosis not as one of exclusion but in a positive way. Merely stating what the diagnosis is not and what has been ruled out (not cancer, not arthritis, etc.), is far less satisfying to parents than stating that this pattern (the location, the family history, the time course, the quality of the pain, the negative physical examination, the lack of red flags for organic disease) supports a functional pain diagnosis. Obviously, the clinician cannot be completely certain that there is not an organic diagnosis that has been missed and the question of how much testing is enough always arises. This is especially difficult when parents produce case reports from the internet or the neighbourhood in which a rare entity with similar symptoms has been missed by clinicians for years. If after a reasonable investigation, the clinician states that a functional diagnosis is most likely but he or she will continue carefully monitoring the child ('watchful waiting'; Herzog and Harper, 1981) and will pursue new symptoms if they emerge, most parents will be satisfied. Additionally, it is important that the physician not imply that the lack of a clear organic diagnosis suggests a psychological explanation. Although psychological factors should not be dismissed, except in rare cases, the symptoms are the result of a complex interplay of a variety of factors and triggers; therefore, implying solely psychological origin not only distances the clinician from the family, but is in fact incorrect. If families feel that their child's suffering is being trivialized or dismissed, even if that is not the intent of the clinician, many families will then continue their search for an organic explanation subjecting the child to additional often unnecessary testing and adding to their own and the health care system's financial burden.

### Specific content

The nature of the discussion with the family about functional pain problems should be individualized based on the educational, social, and cultural characteristics of the family. Regardless, the complex nature of pain and the biopsychosocial dimensions should be

emphasized. The key element is that a number of factors (inflammation, infection, genetic predisposition, stress, depression, injury) may have altered the transmission of pain information in the child and that sensation is now the problem, making the child pain vulnerable. Use of key phrases ('the pain is hurting but not harming you'; 'the pain you are experiencing is not protective') as well as the use of analogies is often helpful. There are a number of analogies that are often used (Coakley and Schechter, 2013). The hardware/software discussion (the pain represents a software problem (the pain message) and not a hardware problem (the bowel, head, muscles, etc.)) is helpful in computer-savvy families. Another frequently used analogy is the false alarm analogy—the continuous pain is like a false car alarm—annoying but not representing a genuine problem. Most clinicians develop their own analogies and explanatory models to help families understand this complex concept that does not follow the traditional medical model.

## Typical treatment recommendations

Specific treatment recommendations are available throughout this volume in the sections that address each of the functional pain problems individually. In general, however, regardless of the site of the functional pain problem, a number of elements should be addressed as part of the treatment.

### School reintegration

As mentioned earlier, school absence is a frequent phenomenon in children with chronic pain. For children with frequent absences, the return to school may be highly stressful. Children may assert that they are not worried about returning to school after a prolonged absence, yet concern about missed work and academic performance and promotion, difficulties with concentration due to pain, worries about discussion with peers regarding the reasons for the absence and about being jostled in the hallway, fears of not being believed by other students and teachers along with a host of other considerations create an inevitable anxiety in the returning student who must deal with these issues while not feeling that well.

It is imperative therefore that school reintegration be carefully orchestrated and often gradual. Depending on the country, there may be legal protections available to the student (a 504 plan in the US, for example) which may ease the return. Regardless of how the school re-entry plan is configured, it should be followed religiously. Decisions about school attendance should not be made in the morning when the child reports he or she is not feeling well enough to return to school. School attendance is expected unless the child has a fever or a contagious process. Accommodations can be made regarding the length of the school day and in the workload but the expectation must be that the child attends school every day.

### Sleep

Addressing issues of sleep is imperative. As mentioned earlier, inadequate and often non-restorative sleep is extremely common in chronic pain. A detailed sleep history should be obtained and identified issues should be addressed. Issues of sleep hygiene (getting into bed when tired, no television in the room, etc.) should be discussed. Relaxation strategies are also often helpful and can be taught by the clinician or by a colleague with experience in these techniques. If sleep remains an issue despite the introduction of psychological strategies, a number of pharmacological agents may be considered. In particular, some of the agents typically administered

for pain or spasm often have a side effect of sedation which can be an added benefit of their use if they are taken at bedtime.

### Physical activity

It is not uncommon when one is in pain to limit physical activity. This may occur because of associated pain, anxiety about pain which may occur as a result, depression, or diminished interest in social activities but regardless, it often leads to deconditioning which increases pain and disability. Decreased exercise and weight bearing can also promote osteopenia.

It is often valuable to have a skilled physical therapist evaluate the child's musculoskeletal system to determine whether formal physical therapy may be needed or whether a home exercise programme will suffice. The therapist can also evaluate the need for desensitization and can emphasize the importance of pacing and stretching. He or she can identify particularly tight or weak areas and if the child is hypermobile, can help with strengthening specific muscles to compensate for ligamentous laxity and promote joint stability. If only core strengthening and building endurance are felt to be necessary, then physical therapy may not be necessary and a graduated exercise programme may be substituted. Either way, increasing movement will promote a sense of well-being and an inevitable reduction of pain.

### Addressing anxiety and depression

As mentioned repeatedly, anxiety and depression are often fellow travellers with chronic pain and may have a role in initiating it, maintaining it, or both. Clinicians should address this with families in the context of the numerous factors involved with chronic pain, as opposed to the organic versus psychological paradigm. There is an extensive literature on psychological strategies reducing the arousal in pain sensitive individuals and response to these strategies does not imply psychological causation (Eccleston et al., 2009). The psychologist can teach relaxation strategies, can address catastrophization, and explore the thoughts that might be promoting incapacitation from a nociceptive stimulus. Most paediatric pain programmes employ or are connected to paediatric psychologists and their evaluation should be a critical part of the assessment and treatment of pain in children. Many families may be resistant to this part of the evaluation and they often fear that they will be blamed for their child's pain. As a result, they may state (sometimes quite strongly) that that component of the evaluation is unnecessary as their child's pain is real. It is important to dispel the notion that the purpose of psychological evaluation and treatment in chronic pain is to unearth subtle psychological causation and blame parents for the child's problem. It is to identify every trigger that may promote and maintain pain and to teach techniques to help ameliorate it. Occasionally, psychopharmacological intervention may be necessary as well.

### Attending to other symptoms

Other symptoms may amplify the incapacitation associated with chronic pain, regardless of site. Dizziness, nausea, and fatigue may result from pain but may also potentiate it. If at all possible, these symptoms should be addressed. Often POTS may be associated with these symptoms or with a general sensation of feeling unwell but it is often not considered and orthostatic vital signs are not obtained. Because the treatment of POTS is often relatively straightforward and its amelioration can dramatically help the child's pain and mood, obtaining blood pressure and heart rate measurements both lying down and then standing up should be a routine part of the evaluation of any type of chronic pain.

### Provider communication

Because children with multiple pain problems typically see multiple specialists (neurology for headache, rheumatology for joint and musculoskeletal pain, gastroenterology for abdominal pain, orthopaedics for back pain, cardiologists for POTS) in addition to their primary care providers, it is imperative that a mechanism for communication among providers be developed. Specialists may not address or even ask about other pain sites which they perceive are out of their realm of expertise and assume those will be addressed by others. They may offer suggestions that they perceive are helpful for the specific problem that they are asked to address but may in fact be detrimental to the whole child. Additionally, there is also often significant variability of opinion among providers as to the aetiology, evaluation and treatment of chronic pain problems. Konenjberg et al. (2004) gave 135 paediatricians a series of case scenarios involving chronic pain and asked how clinicians would address them. There was limited consensus on aetiology, on specific diagnostic testing, and on treatment. A similar situation likely occurs in clinical practice as these problems are often quite confusing and subject to multiple diagnostic opinions. As a result, families may feel confused by the lack of clarity among their physicians and continue a futile search for the right answer. Tests may often be unnecessarily repeated and agents prescribed that may interact negatively. It is imperative therefore in situations in which multiple pains exist that the clinical team be in communication and speak, as much as possible, in one voice.

## Conclusion

This chapter has attempted to review the commonalities and overlaps between the common pain problems that children experience, most of which are functional in nature. This area has had limited attention in the past, most likely due to the fact that pain problems are typically evaluated by experts in the specific organ system from which the pain seems to stem and they may not have expertise in pain that stems from other areas. When one looks at these problems from a distance however, there are remarkable similarities in their theoretical aetiologies, in their impact on the child and family, in associated symptoms, and in their treatment. The adequate care of these problems demands an appreciation of the biopsychosocial model which looks at the child as a whole and on a multidisciplinary approach which allows for multiple streams of information to impact on the child's care.

### Case example

Constance Payne is a 15-year-old young woman who was referred to the gastroenterology programme by her primary care provider for longstanding abdominal pain which had recently escalated in intensity. Constance has had periumbilical pain since the age of 12 but recently since high school entry her discomfort had increased. In the past, Constance had missed 1 to 2 days of school a month for her abdominal pain, but in the fall of ninth grade began missing at least one day per week.

The gastroenterologist who evaluated her identified no pattern to her symptoms and no obvious triggers for it. Her physical examination and subsequent laboratory investigation did not offer a specific pathological explanation for her pain nor did the endoscopy that was performed subsequently. A number

of medications were prescribed for Constance including hyoscine and omeprazole which were both ineffective.

During the course of this evaluation, she reported that recently, she had developed an almost continuous headache and she often felt dizzy. Additionally, she described her vision as 'blurry'. She was subsequently referred to a neurologist who ordered a magnetic resonance imaging scan of her head and sent her to an ophthalmologist. None of these investigations yielded an explanation for her pain. Constance began taking ibuprofen to dampen her headache but stated that this medication aggravated her stomach pain. Concern was raised about her dizziness and she was referred to a cardiologist who identified a significant disparity between her heart rate when she changed position from lying to standing. He suggested a trial of salt and increased fluids.

Because of these multiple complaints, Constance became increasingly inactive. This inactivity was aggravated by additional reports of aches in her neck, knees, and back. She became increasingly incapacitated and was referred to an orthopaedic surgeon and rheumatologist, neither of whom could explain her pain and deterioration. Her sleep became increasingly disordered and she began napping during the day and having difficulty falling asleep at night and awakening in the morning. She complained of crushing fatigue.

Constance and her mother began appearing frequently in the emergency department because, according to her mother, 'something has to be done'. Two of these visits ended in hospitalization for observation and pain control. Constance began losing interest in friends and in activities that had previously brought her pleasure.

With all of these complaints and no explanation, Mrs Payne began to express her worry that her cadre of doctors was missing something essential that would explain this unique constellation of findings. She herself had a cousin who had similar symptoms and was eventually found to have a serious underlying disease. She stated that in September she had a healthy daughter who did well in school and was an excellent athlete. Now, Constance can barely care for herself. Even though she herself has fibromyalgia, Mrs Payne feels she has to stay home and care for Constance. She reports as well the fact that although Constance sees many doctors, her physicians never seem to talk to each other and she feels the overwhelming burden of coordinating her daughter's care due to her fear that something will be missed if she is not perpetually vigilant.

## CHAPTER 24

# Non-inflammatory musculoskeletal pain

Jacqui Clinch

### Summary

Non-inflammatory musculoskeletal pain is common in children and adolescents, and when persistent or widespread, can have a negative impact on physical and psychological well-being. Diagnostic labels and criteria are not uniform in the current literature, but musculoskeletal pain may present as widespread pain or juvenile fibromyalgia, complex regional pain syndrome, or in association with joint hypermobility. Chronic musculoskeletal pain, irrespective of its trigger, can bring persistent and recurrent distress, disability, and widespread family disruption. Once serious medical causes have been excluded by history, examination, and relevant investigations, the focus should be on rehabilitation. Multidisciplinary team management to facilitate cohesive working and the introduction of psychological and physical therapies can improve outcome. Further research is required to define the role of pharmacological interventions.

### Introduction

The most common chronic musculoskeletal pain conditions reviewed in paediatric rheumatology settings include diffuse idiopathic musculoskeletal pain (DIP; also called juvenile fibromyalgia or chronic widespread pain), chronic pain related to childhood joint hypermobility, complex regional pain syndrome (CRPS), chronic back pain, and persistent joint pain following previous or controlled inflammation (e.g. juvenile idiopathic arthritis (JIA)) (Malleon and Clinch, 2003; O'Sullivan et al., 2011).

For many young people presenting to clinic, regardless of whether the cause of their pain is known, the chronic experience of pain has often had a large and wholly negative impact on their physical and psychological well-being, and their family (Malleon and Clinch, 2003). Children who suffer persistent musculoskeletal pain and other symptoms also have a significant chance of developing chronic widespread pain and pain-associated disability in adult life (Jones et al., 2007).

This chapter will review: (1) the epidemiology of musculoskeletal pain in childhood, (2) evaluation of the impact of chronic pain, (3) the clinical features of common pain presentations and their relevance to diagnosis and treatment planning, and (4) rehabilitation interventions aimed at the management of chronic musculoskeletal pain.

### Epidemiology

There is limited data on the prevalence and incidence of musculoskeletal pain in youth, and on the prevalence of pain-associated suffering or disability. However, pain is a common experience during childhood. One study showed that 83% of school-aged children had experienced an episode of pain during the preceding 3 months (Roth-Isigkeit et al., 2005). Pain is a normal sensation but becomes disabling when it persists and is associated with suffering. In this same study, 30.8% of the children and adolescents stated that the pains had been present for over 6 months. Musculoskeletal pains accounted for 64% of all the pains that were reported (Roth-Isigkeit et al., 2005). Other studies support this finding (Brattberg, 2004; Perquin et al., 2000).

- ♦ The epidemiology of DIP (also referred to as juvenile fibromyalgia or chronic widespread pain) is difficult to accurately assess. There are no universally agreed diagnostic criteria, although some authors have suggested using the term juvenile fibromyalgia and proposed diagnostic criteria akin to the adult fibromyalgia criteria (Kashikar-Zuck et al., 2006). The HUNT study (Hoftun et al., 2008) showed 8.5% of a population of 7373 adolescents in Norway fulfilled the criteria for DIP; whereas a UK study showed the prevalence of chronic widespread pain in 17-year-old school children to be 4.3% (Deere et al., submitted).
- ♦ Hypermobility, as currently defined, is present in 19.8% of the normal UK adolescent population (Clinch et al., 2011). There is a relationship between localized pain and significant hypermobility (Beighton score 6 or above); this is discussed later in the chapter (Tobias et al., 2013).
- ♦ Low-back pain (LBP) is commonly reported. A UK observational cohort study reported the prevalence of LBP as 16.3% in 17-year-old adolescents (Deere et al., submitted). A cross-sectional study of school-age children showed prevalence of LBP that lasted for at least 1 month was 24% (Watson et al., 2002), the HUNT study showed this to be 16.7% for girls and 11% for boys (1 day a week for at least 3 months; Hoftun et al., 2011).
- ♦ The prevalence of CRPS in adults is 26 per 100 000 person years (De Mos et al., 2007). In children the epidemiology has not been robustly evaluated but recent studies have demonstrated that approximately 90% of the cases reported are females in a range of 8 to 16 years (Sherry et al., 1999). There tends to be a delay in

recognizing the diagnosis (Stanton Hicks, 2010). A complicating factor is the lack of clear diagnostic criteria for children.

- ♦ In JIA it is clear that persistent pain is a significant problem for many children (Anthony et al., 2007). Approximately 40% describe pain 5 years after diagnosis (Lovell and Walco, 1989). A significant minority progress to develop localized or diffuse musculoskeletal pain that is not directly related to the control of their inflammatory condition (Haverman et al., 2012).

Looking generally across studies a number of features are clear:

- ♦ Girls experience more musculoskeletal pain than boys (Groholt, 1994; Hoftun et al., 2011).
- ♦ Children living in low-educated, low-income families have a 1.4-fold increase in the odds of having back pain (Groholt et al., 1994).
- ♦ The incidence of chronic widespread musculoskeletal pain peaks in older adolescence (Hoftun et al., 2011).
- ♦ Multiple common symptoms (including joint pain, headaches, abdominal pain) in childhood are associated with a moderately increased risk of chronic widespread pain in adulthood (Jones et al., 2007).

## Clinical features of chronic musculoskeletal pain

As many features of musculoskeletal pain conditions are shared by most children, it is appropriate to describe the general presentations at this stage, and then concentrate on specific pain-related conditions in their own right.

### General features

It is not unusual for musculoskeletal pain to start in a localized area of the body (Buskila and Neumann, 2000). The pain can intensify and radiate to other areas. It is associated often with a reluctance to mobilize, and avoidance of movement. In adults, avoidance and fear of pain and movement can reduce fitness and further increase in pain (Elbaz et al., 2009), but in children this occurs on the background of a musculoskeletal system that is still developing. Discomfort and pain intensity increase and become constant. As discrete pains multiply and continue, the young person may avoid contact with, or use of, an area of the body affected, and this can then lead to muscular spasms, and abnormalities of posture and gait. As gait alters, the resultant asymmetry can lead to other vulnerable sites (including lower lumbar, anterior knee, and lateral aspect of pelvis) taking an altered load and causing further discomfort. Over time, affected limbs may adopt flexed positions, and tendons tighten, further exaggerating imbalance and pain.

### Associated symptoms and signs

- ♦ Hypervigilance and pain sensitivity that is greater than expected from a given physical trigger. Children often report a heightened awareness of pain and pain associated cues (American Pain Society, 2012; Malleson and Clinch, 2003; O'Sullivan et al., 20011). It is unclear whether this is caused by fear of pain, or increased sensitivity of pain signalling. Clinically, this presents as young people describing unbearable pain on minimal skin contact, and heightened fear of being touched, for example, on examination.

- ♦ Perceived thermoregulation—this is observed more commonly in adolescent girls. Limbs are particularly cool and mottled. Occasionally there will be areas that are very red and hot to touch on a background of the mottled skin. There may also be an abnormal perception of temperature, but an increase in thermal pain sensitivity has only been documented in adults (Geisser et al., 2003).
- ♦ Autonomic dysfunction—pain is a powerful stressor. Continuous pain signals, immobility, and fatigue act directly on the autonomic system (Cohen et al., 2001). In an environment of physical and emotional anxiety, the sympathetic system is more active. This leads to tachycardia, hyperventilation (compounded with panic attacks), cold sweats, blurred vision, abdominal pain and extreme pallor. Girls particularly complain of nausea, dizziness, and episodes of feeling faint. Children look unwell during these episodes of increased pain. It is not unusual for attending paediatricians to investigate cardiovascular, neurological, and gastrointestinal systems in an attempt to elicit pathology.
- ♦ Musculoskeletal disequilibrium—these young people are still growing, often in their peripubertal growth spurt, and musculoskeletal pain can have lasting effects on the final positioning (Lightman et al., 1987). Proprioceptive signals from the joints are reduced and the limb held in a rigid, fixed position (Sherry et al., 1999; Walco et al., 2010). Legs may 'give way'. Knees and hips are held flexed, feet are inverted, and hands are clenched with flexed wrists. These positions are often described as the most comfortable. Muscles and tendons quickly tighten and this complicates the pain and disability. The adaptive positioning of a young person with leg or abdominal pains particularly affects the gait and resting positions and thus alters the loads on the spine and pelvis.

There are a number of influences on physical behaviour, including psychosocial factors. What can first appear as a structural anomaly or physical constraint may be better explained by fear of pain on movement, or postural compensation due to overprotection of a painful body part. Although an important area, there is very little research of the effects of a chronic stressor such as pain during critical periods of physical development, or in the measurement of movement constrained by pain.

## Specific childhood musculoskeletal pain conditions

### Diffuse idiopathic pain syndromes (juvenile fibromyalgia/chronic widespread pain)

This describes widespread pain, often located over muscles and joints, and with significant pain associated disability (Malleson et al., 2001). The term juvenile fibromyalgia has been used, with diagnostic criteria similar to those used in adults (Hoftun et al., 2011), including a history of widespread pain for at least 3 months, and the presence of 11 of 18 bilateral tender points (occiput, low cervical, trapezius, supraspinatus, second rib, lateral epicondyle, gluteal, greater trochanter, and knees). It should be noted that these American College of Rheumatology criteria have recently been revised and now do not include tender points as it is recognized that widespread pain and related symptoms are good markers for adult fibromyalgia (Wolfe et al., 2010).

The onset of pain in DIP/juvenile fibromyalgia is often gradual. There may have been an initial insult or trauma but often there is no obvious trigger and only vague recollections of the time of onset. The pain is generalized. There may be areas of allodynia (profound hypersensitivity to light touch) and subjective hyperalgesia but there is often an absence of the autonomic changes (including reduced cutaneous perfusion, localized swelling, shiny stretched appearance) seen in more localized pain conditions (O'Sullivan et al., 2011).

What is striking in the young people with diffuse pain is the associated fatigue, poor sleep pattern, and extremely low mood. It is widely believed, however, that low mood in adolescents are reactive (to the pain-associated disability) rather than a primary depression. This is in contrast to adults with fibromyalgia where primary depression is frequently seen (Buskila et al., 1995). Menstrual cycling has been shown to affect fibromyalgia-related symptoms in nearly 50% of adult patients (Pamuk and Cakir, 2005), and this may be relevant in the adolescent female population.

### Complex regional pain syndrome

Although it is almost 20 years since this condition first received attention in children, the diagnosis and treatment of CRPS continues to be poorly understood. Many children receive investigations and rehabilitation for other presumed conditions, resulting in a long journey before CRPS is recognized, and often a worsening of the symptoms and associated disability (Berde and Lebel, 2005; Connelly and Schanberg, 2006). The diagnosis of CRPS remains a clinical one, and in adults is based on the Budapest Criteria (Box 24.1) (Harden et al., 2010). Although there is frequently a precipitating trauma, this is not present in around 10% of cases, and pain is usually out of proportion to the inciting event and accompanied by allodynia (Stanton Hicks, 2010). Children most often describe the pain as burning, with sensations akin to dysaesthesia. CRPS in paediatric patients is clinically distinct from the adult condition (Connelly and Schanberg, 2006; Stanton Hicks, 2010):

- ♦ The lower limb is more commonly involved than the upper limb.
- ♦ There is a marked female predominance.
- ♦ The peak incidence is in early adolescence (median 13 years).
- ♦ Dystrophic changes and long-term disability are less common than in adults.

Signs and symptoms may completely resolve within several months to a few years, but relapses may also occur (Connelly and Schanberg, 2006; Stanton Hicks, 2010). Occasionally more than one limb may be affected at presentation (Stanton Hicks, 2010) or symptoms may progress or migrate to a hand or other leg. This may be due in part to an increase in mechanical load through the arms through the use of crutches and subsequent mechanical pain. Autonomic changes include swelling, reduced cutaneous perfusion, and thermodynamic instability. The affected limb develops a purplish hue with other colour changes that can cause concern to the child and family (Figure 24.1). The skin takes on a shiny, stretched appearance, with coarse hairs developing in patches (Harden et al., 2010). In rare cases, severe trophic changes develop with ulceration and marked wasting. Figure 24.2 shows the marked changes on thermography (reduction in cutaneous blood flow represented

#### Box 24.1 Budapest clinical diagnostic criteria for complex regional pain syndrome

1. Continuing pain, which is disproportionate to any inciting event.
2. Must report at least one symptom in *three of the four* following categories:
  - a. *Sensory*: reports of hyperesthesia and/or allodynia.
  - b. *Vasomotor*: reports of temperature asymmetry and/or skin colour changes and/or skin colour asymmetry.
  - c. *Sudomotor/oedema*: reports of oedema and/or sweating changes and/or sweating asymmetry
  - d. *Motor/trophic*: reports of decreased range of motion and/or motor dysfunction (weakness, tremor, dystonia) and/or trophic changes (hair, nail, skin).
3. Must display at least one sign at time of evaluation in *two or more* of the following categories:
  - a. *Sensory*: evidence of hyperalgesia (to pinprick) and/or allodynia (to light touch and/or deep somatic pressure and/or joint movement).
  - b. *Vasomotor*: evidence of temperature asymmetry and/or skin colour changes and/or asymmetry.
  - c. *Sudomotor/oedema*: evidence of oedema and/or sweating changes and/or sweating asymmetry.
  - d. *Motor/trophic*: evidence of decreased range of motion and/or motor dysfunction (weakness, tremor, dystonia) and/or trophic changes (hair, nail, skin).
4. There is no other diagnosis that better explains the signs and symptoms.

N. et al., Validation of proposed diagnostic criteria (the 'Budapest Criteria') for complex regional pain syndrome, *Pain*®, Volume 150, Issue 2, August 2010, pp. 268–274 with permission of the International Association for the Study of Pain® (IASP). The figure may NOT be reproduced for any other purpose without permission.

by lack of heat detected) of the wasted, flexed, ulcerated foot that is shown in Figure 24.3. Magnetic resonance imaging (MRI) changes early in the condition can show bone oedema that may be confused with other musculoskeletal conditions. Later radiology may show osteopenia secondary to disuse (Berde and Lebel, 2005). Limbs can become distorted and feet/hands held in seemingly fixed and often flexed positions.

While the pathophysiology of CRPS is poorly understood, a number of aetiologies have been proposed: a peripheral small fibre neuropathy, autonomic dysfunction, and exaggerated regional inflammation (Stanton Hicks, 2010). However, inflammatory aspects differ from those seen in other conditions involving tissue inflammation. The suggestion that CRPS in children is a different clinical entity than that seen in the adult, is probably incorrect, as recent evidence would suggest that the pathophysiology is most likely to involve similar endocrine, behavioural, developmental, and environmental factors (Stanton Hicks, 2010). Many features, particularly the neurological abnormalities, suggest both peripheral

and central nervous system (CNS) involvement, and considerable CNS circuitry changes have recently been shown with functional MRI in young people with a diagnosis of CRPS (Lebel et al., 2008).

### Back pain

Recent research has shown that the prevalence of LBP has increased among children and adolescents ranging from 16.4% to 36% (Deere et al., submitted; Kjaer et al., 2011). Mid-back pain and neck pain are also frequently seen (9.4% and 8.9% respectively of adolescent population; Deere et al., submitted) but the literature evaluating these areas is less robust.

**Figure 24.3** Wasted, ulcerated left leg in advanced CRPS.

Factors related to LBP in children and adolescents include:

- ♦ LBP is more common among girls and increases with age (Kjaer et al., 2011; Watson et al., 2002).
- ♦ Risk factors are poor physical condition, reduced strength in muscles that support the back (Diepenmaat et al., 2006), intensive sports (Lundin et al., 2006), and reduced hamstring length (Sjolie, 2004).
- ♦ A prospective study of adolescents showed a strong correlation between LBP, emotional and behavioural problems, as well as other physical problems such as headaches, stomach aches, sore throat, and fatigue (Watson et al., 2002).

The vast majority of children with LBP who come to paediatric rheumatology clinics improve with physiotherapy; however, a minority proceed to develop increasing pain-related disability (Ahlqwist et al., 2008). Chronic pain among adults may, in part, be rooted in untreated painful experiences in childhood and young people who have suffered from LBP are more likely to suffer from these problems as adults (Kjaer et al., 2011).

Few treatment studies on children and adolescents with LBP have been published. One study of children and adolescents shows that individual assessment and follow-up, including an active treatment intervention by an experienced physiotherapist, improves self-perceived health and function and reduces pain, while increasing mobility and strength (Ahlqwist et al., 2008). Another study shows that an exercise programme tailored for children and adolescents with recurrent non-specific LBP has beneficial effects, including reduced pain intensity (Jones et al., 2007).

Red flags for pathology include nocturnal pain, presentation in young children, or neurological symptoms indicating nerve compression/damage. These cases should be fully investigated to exclude:

- ♦ Malignancies (e.g. sarcoma, neuroblastoma, metastases).
- ♦ Vertebral damage (trauma—accidental and non-accidental).
- ♦ Infection (osteomyelitis, abscess) and inflammation (arthritis, discitis).
- ♦ Rare conditions such as chronic recurrent osteomyelitis, Langerhans' histiocytosis, and collapse secondary to iatrogenic or idiopathic osteoporosis.

## Juvenile idiopathic arthritis and pain

Despite significant advances in medical treatments for children with JIA, persistent pain is a common complaint (Anthony and Schanberg, 2007; see also Chira and Schanberg, Chapter 22, this volume). Pain has been shown to be a primary determinant of the physical, emotional, and social functioning in these children (Anthony and Schanberg, 2007). The degree of disabling pain does not always mirror inflammatory joint activity, and a growing body of research highlights the importance of environmental and cognitive behavioural influences in the pain experience of children, in addition to the contribution of disease activity (Connelly et al., 2010; Vuorimaa et al., 2009).

## Idiopathic chronic limb pains

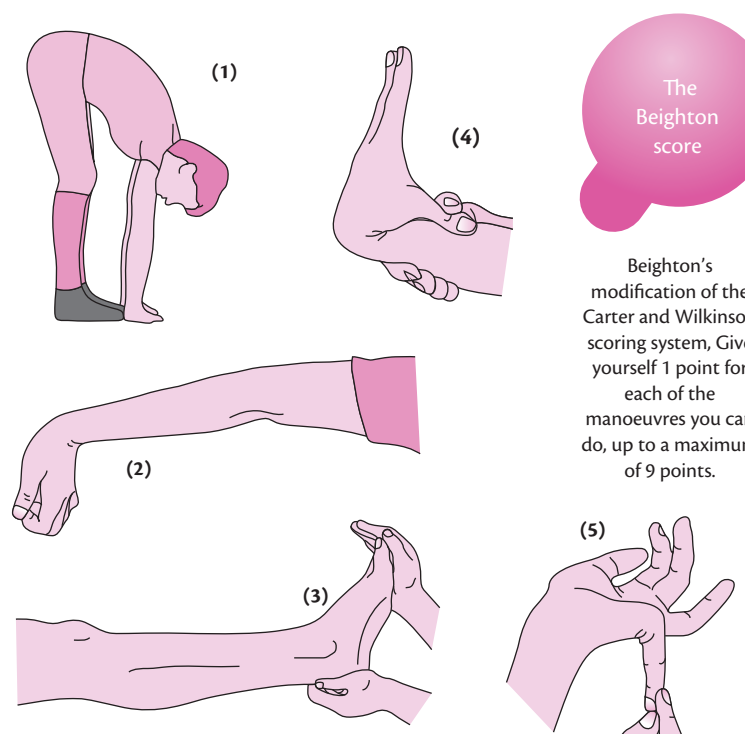

There are many presentations of musculoskeletal pain in children that do not meet the criteria for DIP/juvenile fibromyalgia or CRPS. These include the poorly understood 'growing pains', described as recurrent, bilateral, non-articular pain in the lower extremities that occur late in the evening or at night. They have been observed to coexist with vascular pain problems including migraines, leading

to speculation that there may be a vascular component to the bone pain experienced. A recent small study challenged this theory (Hashkes et al., 2005). Others describe growing pains as a form of overuse injury (Friedland et al., 2005). The jury remains out.

## Joint hypermobility and pain

Joint hypermobility results from ligamentous laxity and may occur in individuals with a primary genetic disorder affecting connective tissue matrix proteins (e.g. osteogenesis imperfecta or Marfan's syndrome) or other syndromes (e.g. trisomy 21, bony dysplasias, or velocardiofacial syndrome). In the majority of cases, hypermobility exists as an isolated finding (referred to as 'generalized joint laxity'), but it may also be associated with musculoskeletal symptoms such as pain and 'clicking joints' in the absence of known genetic causes, in which case it is referred to as 'hypermobility syndrome' (Clinch et al., 2011).

A method of examining and scoring for hypermobility (Figure 24.4) was developed by Beighton in 1973 (Beighton et al., 1973). The Beighton score was devised in South Africa and based on 1083 Tswana Africans and has subsequently been used internationally to define generalized joint laxity in all populations and all age groups. It has not been validated in children.

The  
Beighton  
score

Beighton's modification of the Carter and Wilkinson scoring system. Give yourself 1 point for each of the manoeuvres you can do, up to a maximum of 9 points.

	SCORE	
	Left	Right
1. Can you put your hands flat on the floor with your knees straight?.....	1	
2. Can you bend your elbow backwards?.....	1	1
3. Can you bend your knee backwards?.....	1	1
4. Can you bend your thumb back on to the front of your forearm? .....	1	1
5. Can you bend your little finger up at 90° (right angles) to the back of your hand? ...	1	1
	<b>9</b>	

**Figure 24.4** Calculation of the Beighton score.

It is widely believed that children are more flexible than adolescents, but there is very little supporting literature. For example, one rigorous population-based study from Sweden (Jansson et al., 2004) investigated 1845 children aged 9, 12, or 15 years from 48 geographically randomly selected schools and showed that at all ages, girls had a higher degree of generalized joint laxity as assessed by the modified Beighton criteria. Girls had the highest degree of general joint laxity at the age of 15 years, whereas joint laxity in boys decreased with increasing age. Similarly, a study of high school basketball players (Quatman et al., 2008) showed that after the onset of puberty, girls exhibited greater joint laxity than boys. A recent robust UK population-based cohort study showed that the prevalence of generalized joint laxity in girls and boys (mean age 13.8 years) was 27.5% and 10.6%, respectively, when the commonly used cut-off of four hypermobile joints from the modified Beighton 9-point scoring system was used (total of 1156/6022 children; Clinch et al., 2011). This is arguably within the normal variance of the adolescent population, and suggests that a higher cut-off (such as  $\geq 6/9$ ) or a new, more meaningful measure is needed.

The extent to which generalized joint laxity is associated with significant clinical sequelae, including joint pain, is unclear. A proportion of children noted to be hypermobile can present with recurrent lower-limb arthralgia, anterior knee pain syndromes, and back pain. The prevalence of pain among children with generalized joint laxity has been reported to range from 30% (El-Garf et al., 1998) to 55% (Qvindesland and Jonsson, 1999). However, reports linking hypermobility with joint pain in school children suffer from problems with sample size, methods of assessing hypermobility, and methods of assessing pain. By contrast, a cross-sectional study of schoolchildren showed no association between joint laxity and pain (Leone et al., 2009). A recent evaluation of over 4000 17-year-old adolescents using a higher cut-off for the Beighton score ( $\geq 6$  joints) showed that there is a relationship at this age between hypermobility and pain in the knees and shoulders. There was no relationship between hypermobility and chronic widespread pain/fibromyalgia or back pain (Tobias et al., 2013). A large cohort study has also shown a positive association between generalized joint laxity (Beighton score  $\geq 6$ ) and habitual levels of physical activity, body mass index, and maternal education in girls (Deere et al., submitted).

What seems clear is that the majority of hypermobile individuals will not have significant pain or have any risk for specific musculoskeletal disorders (including osteoarthritis) in later life. Screening tools such as the Beighton score are likely to be inadequate in children as they are generally more mobile than adults (Deere et al., submitted). The challenge remains to interpret symptoms correctly as being related to the joint hypermobility and to predict why some children become symptomatic. The answer is likely to involve physiological and psychosocial factors.

## The impact of chronic musculoskeletal pain on the child and family

Chronic musculoskeletal pain, irrespective of its trigger, can be associated with persistent and recurrent distress, disability, adult attention, and widespread family disruption (Perquin et al., 2000). Pain-related anxiety in JIA is a significant problem for many children and independently affects their social development (Gauntlett-Gilbert et al., 2013a). Most families have relatively successful

mechanisms for dealing with short-lived demands or disruption. However, a young person with significant musculoskeletal chronic pain typically demands sustained physical, emotional, and financial resources (Roth-Isigkeit et al., 2005). Young people with musculoskeletal chronic pain report sleep disturbance, disordered mood, appetite disruption, low feelings (depression is often masked in this population), social isolation, and unwelcome dependency on parents. These are experienced chronically and can serve to maintain pain and disability. They are also difficult to manage in isolation from other symptoms. Adolescence is by definition a time of change and experimentation; adolescents with chronic pain report that they are less socially developed on virtually every metric than their peers (Eccleston et al., 2008).

Parents also report significant distress from living with a child in persistent pain. Levels of parental stress are clinically significant (Eccleston et al., 2004) and parents experience severe distress and conflict in parenting their child. Typically, they report struggling with the desire to cure their child's pain, and comfort their child, recognizing that the desire to protect may be counterproductive (Jordan et al., 2007).

## Managing chronic musculoskeletal pain in childhood/adolescence

### Assessment

History, examination, and investigations are required to exclude significant underlying disease. Although it is common and necessary to be clinically conservative and investigate multiple potential causes, if prolonged this can also lead to a diagnostic vacuum and lack of treatment planning that allows for fear, disability, and depression to grow. With serious medical causes excluded one can then safely move on to rehabilitation. In paediatric practice this may be more difficult as there can be a tendency to catastrophize about persistent pain by the family, and sometimes by the physician. The need to find a cause for the pain can be overwhelming and, in this way, the child may be subject to a large number of medical investigations and interventions that are, at best, not appropriate and cause anxiety. For example, adolescents commonly present to paediatric rheumatology clinics with back pain; it is important to rule out pathology including malignancy and inflammation but to then move forward swiftly with reassurance and rehabilitation. All too often children are moved between different specialities and have further investigations over a long time period; in many instances this causes delay in rehabilitation and increased disability (Clinch and Eccleston, 2009).

### History

For the physician, the goals of history taking are to exclude serious possible causes, identify key problems, build a trusting relationship with the patient (and family), and, if possible, identify a treatment plan. The main differential diagnoses in musculoskeletal pain are trauma, inflammation, infection and malignancy (Box 24.2). Many children with persistent musculoskeletal pain not only have a chronic experience of pain and distress, but a chronic experience of medical settings, feelings of being doubted, having the validity of their pain contested, and often a history of failed and pain exacerbating interventions. Three key psychological features of this setting are worth keeping in mind:

**Box 24.2** Key pathology to exclude in musculoskeletal history**1. Inflammation:**

- a. JIA: pain centred around joint but may be poorly localized (particularly in younger children). Usually more severe in morning and accompanied by stiffness. Reports of joint swelling in peripheral joints. Inflammatory backpain (including sacroiliitis) worse in morning and can wake child up at night.
- b. Discitis: inflammation of vertebral discs. More common in young children. Severe back pain, worse on movement and can wake at night.
- c. Myositis: inflammation of muscle groups. Muscle pain and fatigue. May follow infection or a presenting feature of rare conditions such as juvenile dermatomyositis (rash will accompany this).
- d. Chronic recurrent osteomyelitis: rare inflammatory condition affecting discrete portions of bone. Severe bone pain, may wake at night. Bone swelling seen if severe (particularly on clavicle).
- e. Osteoid osteoma: benign painful lesions in bones. Pain at any time. May wake at night. Localized.

**2. Infection:**

- a. Septic arthritis: usually acute presentation but can persist. Hot, swollen, painful joint. Child may be systemically unwell.
- b. Infective osteomyelitis: again usually acute but can develop Brodie's abscess and persistent bone pain if not identified early.
- c. Tuberculosis: TB can seed in the spine (Potts disease) or joint and cause persistent pain/swelling. A history of travel or contact is important.

**3. Trauma:**

- a. Accidental: enquire about any accidents, sporting injury. This can be missed.
- b. Non-accidental injury: it is extremely important that unusual musculoskeletal pain patterns or inconsistent history of events is investigated.
- c. Osteogenesis imperfecta: these children may have a history of bone pain with no or very little trauma. They suffer multiple fractures.

**4. Malignancy:**

- a. Haematological malignancy: bone pain (night and day) and effusions can be the presenting features of leukaemia.
- b. Osteosarcoma, Ewing's sarcoma: localized persistent pain (day and night).
- c. Neuroblastoma: often in younger children. Localized joint pain with or without history of swelling.

Note: a full medical history is important to exclude other diseases associated with joint pain (including inflammatory bowel disease, cystic fibrosis).

- ♦ Both child and family are likely to be fearful, hoping for a cure, desperate to be helpful, but often 'on their best behaviour', so may not immediately appear to be distressed, and may have flat or neutral affect.
- ♦ Because of their history, any attempt to shift the treatment goal from one of cure to management or symptom control may be heard to be patient and carer(s) blaming, and so should be done only after building trust.
- ♦ What matters is not necessarily what information has been given to the patient and carers, but what they believe to be true. Typically both patient and family will have heard a variety of stories about what may be happening to them (Clinch and Eccleston, 2009). For example, a family who have a child with many painful joints and associated disability may have family members or friends who have a history of bone pain related to other pathology (arthritis, cancer, infection, etc.). Despite reassurance this fear often remains. Inconsistent messages from health professionals and repeat investigations serve to reinforce the anxiety.

**Physical examination**

Time spent on full physical examination at the beginning may prevent repetition and unnecessary, distressing investigations at a later date (Anthony and Schanberg, 2007; Clinch and Eccleston, 2009). If there is concern regarding the diagnosis, then this is the time to order all investigations and ensure that these are followed up. Undue delay leads to fear and often a worsening of pain symptoms and associated disability. On assessment a full musculoskeletal examination would show evidence of, and target investigations to rule out:

- ♦ Inflammation (including JIA, myositis, myopathy, connective tissue disease, chronic recurrent multifocal osteomyelitis).
- ♦ Infection (including septic arthritis, infective osteomyelitis).
- ♦ Malignancy (including osteosarcoma, Ewing's sarcoma, leukaemia, neuroblastoma).
- ♦ Trauma (including non-accidental injury).

Paediatric GALS screening (child version of the Gait, Arms, Legs, and Spine adult examination) is a musculoskeletal examination that can be completed within a short time period on children of all ages (Foster et al., 2006; <<http://www.arthritisresearchuk.org/health-professionals-and-students/video-resources/pgals>>).

**Psychometric instruments**

Musculoskeletal pain intensity in children has long been measured using simple severity measurement tools, such as the visual analogue scale (VAS; Carlsson, 1983; see von Baeyer, Chapter 36, this volume). These give a subjective measure of the pain intensity according to the adolescent and/or pain perceived by their carer. While useful measures, they give no indication of the impact of pain on the young person's life (see Tham et al., Chapter 41, this volume). Two recently developed multidisciplinary tools that have been validated in JIA-related chronic pain and the more general paediatric pain population include:

- ♦ Bath Adolescent Pain Questionnaire (Eccleston et al., 2005) for measuring the impact of pain on adolescents with chronic pain (now used in many tertiary paediatric rheumatology settings).
- ♦ Bath Adolescent Pain Questionnaire for Parents (Jordan et al., 2008) for measuring the impact of adolescent chronic pain on parents.

### Physiological measures of pain-related indices

There are little data on the role or utility of measuring physiological processes in the context of childhood chronic musculoskeletal pain. The role of thermography and bone scintigraphy in CRPS has been studied (Goldsmith et al., 1989; Lightman et al., 1987) in the early and late stages of this pain condition, but opinion is divided on their usefulness. Functional MRI has recently been shown to be a useful tool in evaluating CNS changes in childhood CRPS (Lebel et al., 2008). Quantitative sensory testing (QST) is a valuable tool for assessing sensory perception (including pain) in children (Blankenburg et al., 2010; see also Hermann, Chapter 40, this volume).

### Rehabilitation and self-management

The primary treatment approach to the young person with chronic musculoskeletal pain is one of symptom management and psychosocial rehabilitation. Although it may be tempting to focus solely on the amelioration of the suffering of the child, one of the most important aspects of rehabilitation is 'inclusion'. A dedicated team that works consistently with the adolescent and family will facilitate communication, ensure effective delivery of therapy, reduce iatrogenic influences and enable goals to be reached earlier (Christie and Wilson, 2005; Walco et al., 2010; see also Birnie et al., Chapter 12, this volume). Most approaches to rehabilitation share common features that include education, symptom control, behavioural science and physical therapy. How these strands are delivered is debated. Certainly early recognition and intervention in an outpatient or inpatient setting is key and, in most cases, leads to a more favourable outcome (Anthony and Schanberg, 2007).

There is no current evidence favouring a dedicated outpatient over inpatient service for musculoskeletal pain; however anecdotally it is reported that treating children away from busy acute settings and keeping them in their local area, if possible, is beneficial (Clinch and Eccleston, 2009; Eccleston et al., 2003).

Dedicated pain residential units are able to provide physical and psychological intense treatment for children with significant pain associated disability. Musculoskeletal pain comprises approximately 60% of the presenting conditions in these units and over 80% of the children have related limb/back pain. Outcomes from these units show that pain does not significantly change but function (including back to school), anxiety and coping is measurably improved (Eccleston et al., 2003). Recently the role of parents in pain behaviour has been evaluated (McCracken and Gauntlett-Gilbert, 2011), and parents are key in rehabilitation plans. Specific parent programmes in residential pain centres have been developed and show that changing parent behaviour and responses to their child's pain, assists the child moving on to more optimal outcomes (Gauntlett-Gilbert, 2013a; McCracken and Gauntlett-Gilbert, 2011).

### Education

Although the evidence for education alone as a treatment for behaviour change is lacking, the provision of a rationale for what are often counter-intuitive instructions in self-management is essential. Additionally, one should never underestimate that the average understanding of musculoskeletal anatomy and physiology is often limited. A critical first step in rehabilitation is to offer, reoffer, and reinforce an understanding of how one's body may be working to maintain pain.

Education about pain may be difficult to grasp because there is a dominant cultural view of pain in joints and muscles as a warning sign that a disease process or abnormality is present, and there is often a need for the young person and family to identify a cause. Education can play a valuable role as a fear reduction strategy, providing information to counter beliefs that they have a unique medical complication, or that their symptoms are related to an underlying mysterious disease (Clinch and Eccleston, 2009). Children and their parents often have inflexible or rigid ideas not only about the cause of pain, but also of pain as an important signal of damage or disease. Back pain is extremely common but rarely related to malignancy or arthritis. It can be helpful to show and reinforce to the family the fact that many childhood pains have no function, or have outlived their usefulness. Rhetorical devices (metaphors, stories, examples, pictures) that counter this rigid thinking can be helpful. Explaining the fascinating case of phantom limb experiences can also be helpful, to introduce flexibility to the idea that brain signals must signify peripheral damage.

### Pharmacotherapy

Many analgesics and different interventions have been used for children with chronic musculoskeletal pain, but are not supported by well-controlled therapeutic trials. It is becoming widely accepted, however, that any analgesic intervention should only be used alongside multidisciplinary therapy (Eccleston et al., 2003, 2009).

### Psychological therapies

A Cochrane systematic review reported that psychological therapies are effective for headache and may improve pain control in children with musculoskeletal pain (Eccleston et al., 2009). Small studies using cognitive-behavioural therapy (CBT) in juvenile fibromyalgia (chronic widespread pain) show significant improvement in the child's confidence with managing the pain, but disappointing effect on functional disability and depressive symptoms (Kashikar-Zuck, 2006; see also Logan et al., Chapter 50, this volume). For children who have significant pain-associated disability (school absence, limited mobility, lost independence, extremely low mood, disturbed sleep) there are no randomized controlled trials of multidisciplinary multicomponent CBT; however, there is evidence that an interdisciplinary programme has a positive impact for adolescents disabled with chronic pain (Eccleston et al., 2003). The role of the physician is often as an educator, to oversee analgesic withdrawal and to support the overall message that it is safe to increase activity despite pain and reduce reliance on medical support (Clinch and Eccleston, 2009).

### Physical therapies

In conditions such as CRPS, early intensive physiotherapy (including desensitization) with behavioural support can provide dramatic reversal of the presenting signs and symptoms for some patients (Littlejohn, 2004). The aim is accelerated mobilization (Lee et al., 2002), but this is hindered if the diagnosis is delayed and access to appropriate physical and psychological rehabilitation is limited (Littlejohn, 2004). Many cases of diffuse pain will require a gentle, paced approach. In all cases, the increase of activity should be consistent despite the pain. With musculoskeletal pains the more active the musculoskeletal system becomes the more likely the muscle spasms and tightening are to reduce.

Proprioception improves (Lee et al., 2002; Low et al., 2007) and autonomic changes subside. Where possible the young person should work to devise his or her own 'fitness plan'. Using a local gym rather than a hospital physiotherapy gym allows them to start to return to a more normal environment (Eccleston et al., 2003). Working in this consistent and paced manner can be extremely hard for the young person and their parents. The pain invariably continues at the beginning (if not throughout) and motivation is poor. Parental anxiety is high (Lee et al., 2002) and there is a fear that damage will be done. Psychological support during this time is important. The young person will need help setting goals, learning how to communicate pain to peers and family, maintaining motivation on 'bad days', managing low mood, dealing with anger and frustration, and overcoming fears. Often they have not been at school for a long period of time and need help in preparing again for this difficult environment. In some cases, there may be other mental health needs that can be identified and appropriately treated. See also Holsti et al. (Chapter 57, this volume) and Tupper et al. (Chapter 56, this volume) for further details.

There are ongoing studies that show promise with visual counter-stimulation, specifically in patients with CRPS. Mirror therapy, focusing on the hypothesis that incongruence between motor output and sensory input produces CRPS, is being evaluated in adults (McCabe et al., 2003) but there is no data for children.

It is common for young people with musculoskeletal pain to have contact with complementary medicines (often sourced by their parents). While the evidence supporting many of these therapies in children and adolescents is poor (Tsao and Zeltzer, 2005), some children report benefit with topical treatments that are massaged into the painful area (e.g. back pain) (see also Weydert, Chapter 59; Zeltzer, Chapter 60, this volume).

### Natural history and long-term outcomes

The natural history of chronic musculoskeletal pain in children shows that, in many cases, functional and psychosocial outcomes are improved when compared with adults (Bursch et al., 1998; Gedalia et al., 2000). Early multidisciplinary input (including CBT) has been associated with improved outcomes (Eccleston et al., 2003). CRPS in children generally has a favourable prognosis if early physiotherapy is initiated (with psychological support; Sherry et al., 1999; Stanton Hicks, 2010). This is improved if the parents are involved in the rehabilitation process (Gauntlett-Gilbert et al., 2013b). However, a prolonged time to treatment and the presence of marked autonomic changes are poor prognostic indicators in this condition.

### Summary points

- ♦ Untreated complex paediatric pain is personally, socially, and financially burdensome for individuals, families, and societies.
- ♦ Ensure an early, thorough history and physical musculoskeletal examination to rule out new or suboptimally treated pathology in children with chronic musculoskeletal pain.
- ♦ Evaluate the impact of the pain on the child and family (not just the level of pain) so that rehabilitation can be tailored
- ♦ Involve a multidisciplinary team early (ideally in joint clinics) to facilitate cohesive working and the introduction of psychological and physical therapies.

- ♦ Evidence shows that early dedicated therapy can significantly improve the outcome of childhood chronic musculoskeletal pain.
- ♦ Key areas for further research include evaluating the physiology of childhood musculoskeletal pain, the role of parents, and evaluating the efficacy of pharmacological interventions.

### Case example

Anna is a 12-year-old previously well girl, who develops pain in her left ankle following a fall during her gymnastics class. She attends the Accident and Emergency (A&E) department, no fracture is seen on X-ray, and her ankle is bandaged. She is advised to rest, take paracetamol and ibuprofen for the pain, avoid weight bearing and use crutches until the pain settles. One week later, she returns to A&E as she still has severe pain. Repeat X-ray is normal, but her ankle is immobilized in a below-knee cast and she is referred for an orthopaedic opinion at her local hospital. Four weeks later the cast is removed, her lower leg is noted to be swollen, red, warm, and slightly sweaty, and she is still unable to weight bear due to pain. She is given codeine for analgesia, an MRI confirms swelling but there is no localized infection or bony injury. Anna is referred for physiotherapy, but is unable to perform most of the suggested exercises, as her leg is too painful. Over the next 2 months, the pain extends to involve her whole lower limb, her leg is now cold and mottled, and she can no longer wear shoes and socks as the skin is sensitive to touch. Anna can now only walk for short distances with crutches, is using a wheelchair to mobilize, cannot manage at school, and is sleeping poorly.

Both Anna and her parents are concerned that an important diagnosis has been missed, and request referral to another specialist. A bone scan is performed which shows a generalized decrease uptake, and she is commenced on gabapentin for her pain. Despite increasing doses of gabapentin, and continued use of codeine and ibuprofen, Anna's pain does not improve. She is referred to a multi-disciplinary clinic. Anna reports continuing pain, she is unable to tolerate trousers on her left leg, and her leg feels weak. On examination, she is sitting in a wheel chair and is reluctant to stand, her lower leg appears swollen, light touch is painful but her left foot feels colder than the right, and she has reduced range of movement in both the ankle and knee. CRPS is diagnosed, and the nature of the condition and management are discussed with Anna and her parents. Her investigations are reviewed and reassurance given that other diagnoses have been excluded and no further investigations are required. Anna is referred for an intensive rehabilitation programme which includes physiotherapy, psychological interventions, and education. Her parents are still concerned, and angry that it has taken so long for the diagnosis to be made, but agree to attend family sessions during the programme. Despite initial reluctance to do physiotherapy exercises which exacerbated her pain, Anna is given a graded programme, and her mobility gradually improves. Three weeks later, she still has residual pain, but she is able to walk without aids, is weaning off her medications, and her sleep and mood have improved. Prior to discharge, Anna is given instructions about continuing management at home, including the need to deal with potential flare-ups. On review 3 months later, Anna has returned to full-time school and although she had a relapse of pain and swelling in her leg 4 weeks previously, she was able to manage this with increasing exercises and maintained weight bearing.

## CHAPTER 25

# Pain in sickle cell disease

Carlton Dampier and Lamia Barakat

### Summary

Sickle cell disease (SCD) presents a complex pain disorder to clinicians. Pain from vaso-occlusion of sickle erythrocytes can occur in multiple musculoskeletal locations, several internal viscera such as the spleen, as well as the penis. Such pain is typically intermittent in childhood, shares features of acute pain with other pain disorders, and often responds to non-steroidal anti-inflammatory drugs (NSAIDs) and opioid analgesics. Adolescents with SCD often experience more frequent pain, and those with bone disease in spine, hips, or shoulders may experience chronic pain. Like other chronic pain disorders, this pain often responds poorly to opioids, but there is limited current clinical or research data to support alternative medications. Many cognitive-behavioural strategies are helpful as part of multidisciplinary pain management, particularly in adolescents, who may also benefit from psychological support to treat coexistent mood disorders, to increase coping skills, and to support appropriate school and family functioning. Future advances in pharmacological and psychological therapies are needed to ameliorate the substantial burden of pain in children and adolescents with SCD.

### Introduction

Sickle cell disease (SCD) is a complex autosomal recessive disorder of haemoglobin structure characterized by variable degrees of haemolytic anaemia and intermittent episodes of vaso-occlusion that cause or contribute to a variety of acute and chronic complications, and ultimately leads to the development of chronic organ damage. These cumulative disease effects cause significant morbidity, reduced quality of life, and shortened life expectancy. Studies from the former Comprehensive Sickle Cell Centers suggest that it is the occurrence of vaso-occlusive pain that has the strongest negative effect on child or adult-reported health-related quality of life compared to any other acute or chronic SCD-related complications (Dampier et al., 2010a, 2010b). Healthcare utilization for pain management and their associated costs are substantial in this disorder. Yearly estimates of hospitalization frequency in the US range from 70 000 to 90 000, and over 200 000 to 230 000 for emergency department (ED) visits based on data from the Nationwide Emergency Department Sample, most of which (>80%) are for adults, with pain as the major indication (Lanzkron et al., 2010). This ED utilization is three times higher than for congestive heart failure, HIV, or asthma. Lifetime costs for SCD care have been

estimated at over \$US450 000 per individual including home care, and annual charges have been estimated at \$US350 million for ED visits and \$US1 to \$US2 billion for hospitalizations, depending on study methodology (Kauf et al., 2009).

### SCD pathophysiology

The pathophysiology of vaso-occlusion in SCD is quite complex and involves mechanisms beyond sickle polymer formation. One such mechanism demonstrated in *in vitro* systems (Walmet et al., 2003) and in animal models (Embury et al., 2004) is the adhesion of sickle erythrocytes, and perhaps other cellular elements including leucocytes and platelets (Turhan et al., 2002), to vascular endothelium. Their potential importance in vaso-occlusive pain in children has been demonstrated in biomarker studies (Dampier et al., 2004b), and specific anti-adhesive therapies are now being tested in preliminary efficacy studies in both paediatric and adult populations. Cellular adhesion is further enhanced by the release of cytokines from ischaemic tissue injury resulting from vaso-occlusion, which act both by upregulating the surface expression of receptors (interleukin (IL)-1, IL-6, tumour necrosis factor (TNF)), or by increasing integrin avidity (IL-8) (Pathare et al., 2003).

The tissue damage from ischaemia caused by sickle vaso-occlusion is an obvious source of an inflammatory response, and anti-inflammatory agents such as steroids and NSAIDs have clinical efficacy in the treatment of pain in SCD patients. The molecules involved in the inflammatory response likely cause alterations in the properties of peripheral nerves leading to increased spontaneous firing known as 'peripheral sensitization', and the enhanced excitability of nociceptors leads to the development of primary hyperalgesia (see Walker and Baccei, Chapter 6, this volume, for additional details). These consequences of the pro-inflammatory component of vaso-occlusion likely contribute to the challenge in treating pain associated with SCD.

### Epidemiology of pain in SCD

Pain is the most common symptom of SCD, but remains poorly characterized, and can begin early in the first year of life as levels of fetal haemoglobin decline in susceptible individuals. In a prospective longitudinal study of 103 infants with SCD from birth to 7 years of age (Dampier et al., 2010a), the total frequency of days that children had pain was 1.6%. This represented distinct episodes of pain typically lasting several days ( $3 \pm 2.9$  days, range 1–23 days),

of which only 14% required hospitalizations. Over 80% of the children reported to have pain in the 0- to 12-month age interval had pain locations (hands/feet) and signs/symptoms (swelling or tenderness) consistent with dactylitis, which became progressively less prevalent in older age intervals reaching a level of about 10% by age 48 to 60 months. The prevalence of sickle pain occurrence is consistently higher and its duration longer in the children with the typically more severe type of SCD, SS or SB0 thalassaemia, compared to those with the milder SCD type, SC or SB+ thalassaemia, at all age groups. The time to first reported occurrence of pain is also influenced by sickle genotype, and is significantly shorter in children with SS with a mean of  $18.5 \pm 2.5$  months, compared to  $39.0 \pm 4.9$  months for those with SC,  $24.4 \pm 3.8$  months in SB+ thalassaemia, and  $37.9 \pm 11.7$  months in SB0 thalassaemia ( $p = 0.003$ , log rank test). Similar genotype differences are noted for time to the second reported pain event (SS  $21.3 \pm 2.3$  months, SC  $43.5 \pm 4.3$  months, SB+ thalassaemia  $30.3 \pm 3.9$  months, also  $p = 0.003$ ). Longitudinal modelling of pain trajectories over this early childhood period suggests about 70% of SCD infants and young children remain relatively asymptomatic while about 10% to 15% have relatively frequent pain over this period and a similar number develop frequent pain after age 2 to 3 years of age.

Almost all children with SCD experience increasing pain as they progress through childhood into adolescence and young adulthood, but studies suggest that the large majority of these painful episodes continue to be managed at home (Dampier et al., 2002a, 2002b). However, a small minority of children transition, often in their early adolescent years, from sporadic episodic acute pain to frequent recurrent acute pain, and these individuals represent the majority of paediatric patients hospitalized for acute pain (Platt et al., 1991).

There are no studies in paediatric SCD describing the prevalence of chronic pain, but daily opioid usage has been suggested as a surrogate for chronic pain. Data on the self-reported usage of daily oral opioids was obtained from the patient registry (Dampier et al., 2010b) of the 10 SCD programmes of former Comprehensive Sickle Cell Centers Clinical Trial Consortium. Usage was relatively infrequent prior to adolescence, particularly in the SC/SB+ cohort, and widespread throughout the adult age range. The incidence of new onset daily opioid usage was 3% per year, and once initiated was not often discontinued in the subsequent 2 years (<30%).

Pain is a more complex experience in adults with SCD, with features of both acute recurrent and chronic pain. A study of a cohort of adults using daily pain diaries documented that pain was reported on 56% of days and exacerbations of pain (crises) on 13% of days, with almost 30% of patients reporting pain in greater than 95% of diary days (Smith et al., 2008).

## Beyond vaso-occlusion: other pain syndromes in SCD

Other pain syndromes distinct from vaso-occlusive episodes are also common (Table 25.1). Young children with acute splenic sequestration, an often life-threatening trapping of sickled erythrocytes in the spleen, can experience acute left upper quadrant visceral pain from rapid enlargement of the splenic capsule. Older children can similarly experience episodic right upper quadrant colicky abdominal pain and jaundice from cholelithiasis, as chronic haemolysis results in bilirubin accumulation in the gall bladder. Bone infarction leading to avascular necrosis in the vertebral column, shoulder, or hips,

**Table 25.1** Other pain syndromes in sickle cell disease

Syndrome	Body site	Characteristics
Acute bone infarction	Ribs, long bones	Acute necrosis of bone marrow
Acute cholelithiasis	Gall bladder	Acute visceral pain from pigment gallstone irritation or common bile duct obstruction
Acute splenic sequestration	Spleen	Acute visceral pain related to stretch of splenic capsule from rapid splenic enlargement
Avascular necrosis	Hips, shoulders, vertebrae	Progressive collapse of bone cortex related to persistent vascular compromise of cortex and marrow
Headache	Head	Headache pain with or without migrainous characteristics
Leg ulcers	Ankles, feet	Acute and chronic pain from ischaemic damage to skin and underlying soft tissue
Osteomyelitis	Any bone	Bacterial infection of bone cortex or marrow, often related to chronic ischaemia
Splenic infarction	Spleen	Acute visceral pain from splenic infarction involving splenic tissue extending to splenic capsule

can be a source of acute pain as well as chronic pain in adolescent and young adult patients. Physical therapy is often helpful for initial symptom management of hip pain, but some patients will have progressive collapse, particularly in the head of the femur, that will ultimately require joint replacement for relief of chronic pain or to improve physical functioning. While uncommon in the paediatric age group, leg ulcers, typically over the medial malleolus of either or both ankles, can be a source of considerable pain and disability (Minniti et al., 2010). Headaches, as an isolated pain syndrome, or as part of a vaso-occlusive event, are relatively common, but not well characterized (Niebanck et al., 2007). Some have features characteristic of migraine headaches, others may be more typical of tension-type headaches, while a small number of individuals satisfy current diagnostic criteria for chronic daily headache. Headaches may be somewhat more frequent in children with a history of sickle cell-related cerebrovascular events.

## Assessment

Multidimensional assessment of chronic and acute sickle cell and other pain across settings (home, school, and hospital) is the foundation of effective pain management. Age-appropriate pain intensity measures used for other acute pain disorders or for post-operative pain (McGrath et al., 2008) also have been validated in SCD. Inclusion of measures with body diagrams is particularly useful given that multiple sites of pain are often present (Walco and Dampier, 1990). Measures of pain interference with physical functioning, such as the Child Activity Limitation Interview, CALI (Palermo et al., 2004), or the Pediatric PROMIS (Patient Reported Outcome Measurement Information System) pain interference scale (Varni et al., 2010), also may provide additional important information useful in assessing treatment responses.

The importance of including child report of pain is highlighted in sickle cell disease (Graumlich et al., 2001). Limited concordance between child and caregiver sickle pain reports has been noted, similar to other disorders. Parents and children's report of child SCD pain are only moderately consistent and are particularly divergent for interference with activities and pain descriptors (Barakat et al., 2008b). Objective evaluations of sleep (Law et al., 2012) or physical activity with actigraphy (Wilson and Palermo, 2012) may help clarify discrepant reports. Moreover, emerging technologies have provided opportunities to facilitate daily patient report on pain. Electronic assessment was found to be feasible for children and adolescents with SCD to monitor skills practice and daily pain using an electronic handheld device (McClellan et al., 2009). Data were complete when devices were accessed for daily pain diary data entry, and devices were accessed on 76% of pain diary days. Moreover, children, adolescents, and parents were highly satisfied with accessing device to provide information on pain. Similar electronic monitoring to guide analgesic medication usage has been recently described using cell phone technology, and appear particularly promising (Jacob et al., 2012) given the ubiquitous use of cell phones in the adolescent and young adult populations.

## Psychological therapies

Cognitive-behavioural approaches, specifically deep breathing and progressive muscle relaxation, guided imagery, and calming self-talk, have been the most promising psychological therapies to address sickle cell-related and other pain among children and adolescents with SCD (Anie and Green, 2012; Chen et al., 2004). Chen and colleagues (2004), in their review of 22 interventional studies targeting pain and adherence, reported that cognitive-behavioural approaches were superior to educational interventions and probably efficacious in addressing both pain and health care contracts. In contrast, behavioural and educational approaches alone are not sufficient to modify adherence or pain. Findings regarding psychological interventions for SCD are consistent with the broader literature on efficacious interventions for paediatric chronic pain in which a recent meta-analysis indicated the superiority of cognitive-behavioural interventions (multicomponent, relaxation, and biofeedback approaches) to address pain across paediatric chronic pain conditions including SCD (Palermo et al., 2010).

Initial efforts to identify psychological interventions for children with SCD have been promising. Hypnosis delivered in group format and including caregivers over an 18-month period reduced sickle cell-related and other pain for children, adolescents, and adults with SCD (Dinges et al., 1997). In an effort to develop brief pain interventions, Gil and colleagues (Gil et al., 1997, 2001) reported on the results of an intervention for children and adolescents with SCD that was initiated during a clinic visit, and supported through phone calls and taped instructions. The intervention comprised deep breathing relaxation, pleasant imagery, and calming self-talk. Reduced laboratory task-based pain and less negative thinking were reported at the end of treatment. However, at follow-up, the treatment group endorsed more pain but also more active coping. When the children had pain and practised coping strategies, they had fewer health care contacts and missed fewer days of school. Also, the treatment group had less negative thinking on days with low levels of pain.

More recent psychological intervention trials have been guided by reported associations of environmental factors with pain and

functional disability (e.g. socioeconomic status; Barakat et al., 2007; Palermo et al., 2008) and parenting stress as mediator of pain's association with reduced quality of life (Barakat et al., 2008a), which underscores the need to develop family-focused interventions to support communication around and management of SCD complications, in particular pain, to minimize caregiver's distress in response to SCD-related events. Targets of these interventions are more broadly defined in terms of sickle cell knowledge, pain coping and adherence, family functioning, and quality of life. A six-session family psychoeducational intervention (Kaslow et al., 2000) produced improvements in knowledge of sickle cell disease that were maintained at a 6-month follow-up but had no effect on psychological adjustment, family functioning, and social functioning and support. Similarly, four-session, family-based, cognitive-behavioural intervention for adolescents with SCD showed promise in terms of percentage of pain days, disease knowledge, and family cohesion (Barakat et al., 2010); however, both groups reported improved psychosocial functioning, including a decrease in percentage of days with interference with daily activities at both time points, and decrease in pain-related hindrance of goals.

More research is needed to evaluate components that may support maintenance of effects past the immediate post-intervention period and generalization of effects beyond pain to health care contacts, functional ability, and quality of life. In addition, evaluation of format for delivery of the intervention (i.e. therapist-delivered versus self-administered, individual versus group format) and inclusion of family members or other supports is important. Psychological interventions described in the literature were developed for and implemented with children and/or adolescents with SCD; however, no studies of psychological interventions for young children with SCD were identified. Given that parents experience uncertainty about their ability to manage pain at home (Ievers-Landis et al., 2001), interventions that support development of parenting skills that address but do not reinforce pain are essential. Finally, there is a need to evaluate whether tailoring of pain interventions to better match African American values and systems, such as through inclusion of extended family and integration of culturally sensitive content and components, improves the efficacy of psychological interventions for SCD pain (Schwartz et al., 2007). Importantly, related to accessibility of interventions, preliminary data from an Internet-delivered intervention (Palermo et al., 2009) with children and adolescents with chronic pain using a family cognitive-behavioural therapy approach showed significant effects in terms of reduced pain and increased activities maintained through a 3-month follow-up compared to a treatment as usual control group. This interactive, self-paced intervention involved eight online sessions and targeted improved knowledge, skills to address sleep, activity, and pain (relaxation, distraction, cognitive coping skills), parenting skills, and pain communication skills.

A new approach to pain management, that may be effective for children and adolescents with SCD, is acceptance and commitment therapy (ACT). ACT emphasizes the promotion of daily functioning and quality of life while teaching a willingness to experience difficult and possibly unavoidable private events (e.g. pain, discomfort, fatigue, anxiety) without defence when doing so serves valued ends. A recently published case study of a 16-year-old with SCD indicated improvements in pain, functional ability, and quality of life at a 3-month follow-up assessment (Masuda et al., 2011). Further larger studies are in progress.

## Physical therapies

Physical therapies, especially heat therapy, are commonly used to provide symptomatic relief at home (Dampier et al., 2004a), but few such therapies have been subjected to rigorous evaluations. Massage therapy implemented for 20 min per day for 30 days by caregivers resulted in less pain, improved functional status, and lower levels of depression and anxiety during intervention and at immediate post-intervention follow-up for children and adolescents with SCD compared to an attention placebo control group (Lemanek et al., 2009). Unfortunately, caregivers in the massage therapy group had higher depression, suggesting that the demands of the intervention contributed to care provider stress. Transcutaneous electrical nerve stimulation (TENS) has also been studied in a small clinical trial (Wang et al., 1988), and showed some modest clinical benefit during vaso-occlusive pain.

## Pharmacological therapies

### Pharmacology of opioid analgesics in SCD

A unique feature of SCD pain treatment is the impact of chronic anaemia on analgesic pharmacokinetics. One of the normal compensatory mechanisms to chronic anaemia is increased cardiac output with resultant increase in hepatic blood flow, as well as increased renal blood flow and glomerular filtration rate. Many analgesics, such as morphine, that have a component of their metabolic pathway dependent on hepatic or renal clearance will have accelerated plasma clearance in individuals with SCD. Plasma morphine clearances in paediatric subjects aged 6 to 19 years ranged from 6.2 to 59.1 ml/min/kg (mean,  $35.5 \pm 12.4$ ) during steady-state infusions compared to 20 to 25 ml/min/kg in children with cancer or postoperative pain (Dampier et al., 1995). Over the age range studied clearance values were negatively correlated with age. Pharmacokinetic modelling suggested a two-compartment model with a short initial distribution phase (mean half-life = 4.5 min) and a rapid terminal elimination half-life ( $77.6 \pm 19.2$  min). Similarly, in a study of 20 adult SCD patients in steady state (Darbari et al., 2011), a mean morphine clearance of 68 ml/min/kg ( $4.1 \pm 1.1$  L/h/kg) was observed, which is also over twice that typical in adult individuals without SCD. The pharmacokinetics of other analgesics or analgesic adjuvants have not been determined in patients with SCD, but those dependent exclusively or renal clearance, such as gabapentin or pregabalin (Bockbrader et al., 2010) will likely be cleared more quickly so conventional drug dosing recommendations may result in subtherapeutic drug levels in many SCD individuals. These considerations underscore the need to conduct formal pharmacokinetic studies of commonly used analgesic medications and novel investigational agents in this population.

### Home management

Most families prefer to manage their child's vaso-occlusive pain at home, as the home setting is likely to be more comfortable for children and less disruptive to the family. Many families have also experienced negative attitudes towards patients with sickle cell disease by health care providers in the ED setting, often based on a profound fear of catering to opioid addiction, that can compromise analgesic therapy (Zempsky, 2009). Successful home management optimally requires the presence of a caregiver relatively skilled in pain assessment with access to appropriate analgesic medication,

and some extended family support as these episodes may last for several days and usually require around-the-clock medication for adequate management. Home management and appropriate emergency department utilization is also facilitated by access to trusted medical health professionals with experience in sickle cell disease and pain management who can help optimize analgesic therapy. Families need to be reminded to provide these medications on an appropriate time-contingent basis as most studies and anecdotal experience suggest that families administer these medications less frequently than recommended (Dampier et al., 2002b). Since complete pain relief is unlikely, families also need to be counselled on appropriate home therapy goals of maximizing comfort and function while minimizing troublesome analgesic side effects.

Low-potency analgesics, such as acetaminophen or ibuprofen, are typically chosen as initial therapy by most families and are often adequate for less intense pain, particularly in younger children. These analgesics are often chosen out of concern for the adverse consequences of opioid analgesics and have the advantage of little sedation and subsequent disruption of age-appropriate distracting activities.

A substantial variety of oral opioid analgesics of varying potency are available in liquid and tablet formulations for management of more intense pain in children with SCD. However, comparative efficacy or potency data is not available in the SCD population so opioid selection is generally individualized based on patient-specific efficacy and side effect profiles. While labelled dosing and frequency are usually recommended, the enhanced hepatic and renal clearance of morphine in this population (Dampier et al., 1995), the potential impact of prevalent genotypes impacting morphine metabolism (Joly et al., 2012), and the potential occurrence of opioid tolerance suggests that dose and frequency of oral opioids may need to be individualized. There is little published literature or clinical trial experience with the use of newer buccal or intranasal opioid preparations in the SCD population, but these medications may have a more potential useful role for rapid pain relief in the ED setting rather than at home.

There have been few comparative studies of adjunctive non-opioid analgesic medications in this population. The combination of potent opioids and ibuprofen likely provides the most pain relief in the home setting compared to weaker opioid combinations, particularly for older children with more intense pain (Dampier et al., 2002b). An observational study using pharmacy claims data suggested that pharmacological treatments for sickle pain consisted mainly of NSAIDs and weak opioids (Jerrell et al., 2011). Significantly more SCD patients with more than three yearly inpatient or ER visits for pain management were prescribed stronger opioids, antidepressants, and anticonvulsants. Prescriptions of both stronger opioids and antidepressants or anticonvulsants were significantly associated with lower cumulative rates of acute sickle pain visits over time in this cohort. Further clinical trial data is needed to support these clinical findings and establish comparative efficacy and safety data for various analgesic and anticonvulsant or antidepressant combinations, particularly as many of these classes of medications are not currently labelled for use in paediatric age groups.

Families naturally use both medical and psychological interventions to address symptomatic treatment of pain. Several studies of caregivers of children with SCD have found that a large percentage of families use complementary approaches of prayer, spiritual

healing, massage, and relaxation in addition to medication to manage their child's pain at home (Dampier et al., 2004a; Yoon and Black, 2006). In both studies, complementary approaches were used more frequently with higher levels of pain or medication use.

### Management of chronic/persistent pain

In contrast to acute pain management in SCD, the management of chronic pain has not been described, particularly in adolescents and young adults, and management strategies are often extrapolated from adult literature. Currently, such management in SCD has largely relied on use of long-acting opioid preparations, either in oral or transdermal formulations, but there is an increasing realization in the general US adult population that such daily opioid usage is more frequent in individuals with comorbid psychological and psychiatric disorders (Edlund et al., 2010), and has substantial long-term adverse effects, especially in large doses, including a risk for opioid-induced hyperalgesia, addiction, tolerance, constipation, nausea, somnolence, and immune suppression (Hutchinson et al., 2011; Kalso et al., 2004). Studies are needed in paediatric SCD to further characterize appropriate patient selection and dosing for chronic daily opioids, the role of alternative non-opioid analgesics, antidepressants, anticonvulsants, and their long-term health outcomes. Adolescents and young adults with SCD started on daily opioids should also receive concurrent psychosocial and psychiatric support given the role that emotional, social, and psychiatric issues negatively contribute to the pain experience (Sullivan and Ballantyne, 2012).

### In-patient/ED pain management

Authoritative guidelines are available for the management of severe SCD pain in the acute care setting (Benjamin, 1999; Rees et al., 2003), but are somewhat outdated. However, more contemporary single site pain management practices from a number of paediatric hospitals have been published (Morrissey et al., 2009; Zempsky et al., 2008). A recent 'snapshot' of clinical analgesic practice, across a large number of paediatric hospitals participating in an observational study of the development of acute chest syndrome after hospitalization for sickle pain management, suggested the use of opioid-based patient-controlled analgesia (PCA) was the most common analgesic practice (Miller et al., 2012). Opioid doses varied widely, but appeared to be somewhat higher for those individuals receiving PCA compared to time-contingent opioids, and for those receiving hydromorphone compared to morphine. The relationship between opioid dosing and prior daily opioid usage was not described in this cohort, but adult chronic pain patients with chronic opioid use have been shown to report higher postoperative pain scores after surgery and have a slower rate of pain resolution (Chapman et al., 2011), and a similar pattern is likely in sickle cell disease.

Nausea, pruritus, and constipation are common opioid-related adverse effects during such treatment (Dampier et al., 2011b), and require symptomatic management. The use of concurrent low-dose opioid antagonist (naloxone) has been shown in several small cohorts (Koch et al., 2008; Monitto et al., 2011) to ameliorate many CNS opioid-related symptoms without compromising analgesia, and may have particular benefit in SCD where respiratory

depression may enhance the risk for pulmonary complications such as acute chest syndrome. Common GI-related opioid adverse effects may be significantly ameliorated by peripherally acting opioid antagonists, such as methylnaltrexone (Gatti and Sabato, 2012) and similar agents, but they have not been studied in SCD, and are not yet labelled for paediatric patients.

The concurrent use parenteral NSAIDs, usually ketorolac, is a widespread clinical practice in the ED and in-patient setting as an additional analgesic, and may have additional benefit as an anti-inflammatory agent given the increase evidence for the role of inflammation in sickle cell disease pathophysiology (Dworkis et al., 2011), but large scale efficacy studies are lacking and caution advised in those children with SCD and impaired renal function. Evidence of efficacy of other adjuvant analgesics for acute sickle pain, as have been proposed for postoperative pain (Wu and Raja, 2011) have not been subjected to clinical trials. Benefit from concurrent low-dose ketamine has been described in a small case series (Zempsky et al., 2010), and there is anecdotal experience with the use of oral or transdermal clonidine, an  $\alpha$ -adrenergic agonist, to enhance analgesia and to reduce symptoms of opioid withdrawal following prolonged periods of opioid PCA.

## Emerging and future directions in sickle pain

### Prevention of sickle pain

Fundamentally the best way to prevent pain in sickle cell disease is to prevent vaso-occlusion. Current therapy with hydroxyurea is often not able to produce a high enough fetal haemoglobin response to prevent sickling and subsequent vaso-occlusion in some patients, particularly those with relatively low baseline fetal haemoglobin levels. Alternative fetal haemoglobin inducers are being developed based on other mechanisms of action including histone deacetylase inhibitors, and novel thalidomide analogues (Akinsheye et al., 2011; Sankaran, 2011), both of which have entered clinical trials. Rather than reducing sickle polymer formation by decreasing the intracellular sickle haemoglobin content, other approaches to prevent sickling attempt to directly modify the properties of the sickle haemoglobin molecule. A naturally occurring aromatic aldehyde, 5-hydroxymethyl-2-furfural (5HMF) has been shown to form a high-affinity Schiff-base adduct with sickle haemoglobin and inhibits red cell sickling by allosterically shifting oxygen equilibrium curves towards the left (Abdulmalik et al., 2005). This compound has begun phase I/II clinical trials.

An improved understanding of the pathogenesis of vaso-occlusion has led to the targeting of several pathways contributing to vaso-occlusion. Hypoxia from ischaemia leads to alterations in many factors and metabolites which may contribute to the pathogenesis of pain and enhance further vaso-occlusion. Drug discovery approaches have identified that increased adenosine levels promoted sickling, haemolysis and damage to multiple tissues in SCD transgenic mice and promoted sickling of human erythrocytes mediated through adenosine A(2B) receptor (A(2B)R)-mediated induction of 2,3-diphosphoglycerate, an erythrocyte-specific metabolite that decreases the oxygen binding affinity of haemoglobin (Zhang et al., 2011). Antagonists of the adenosine A(2B) receptor are being developed and tested in early phase clinical trials for amelioration of sickle pain.

Similarly, a number of cell surface receptors on sickle erythrocytes or endothelial cells participate in promoting the adherence of blood cells during vaso-occlusion (Kaul et al., 2009). Polymorphonuclear neutrophils (PMNs) also can capture circulating sickle red blood cells in inflamed venules, leading to critical reduction in blood flow and vaso-occlusion suggesting a role for the selectin family of cell adhesion molecules. P-selectin-specific inhibitors (aptamers; Gutsaeva et al., 2011) and pan-selectin inhibitors (Chang et al., 2010) have shown efficacy in animal models of vaso-occlusion, and are also in early phase clinical trials for sickle cell crises.

## Sickle pain pathophysiology

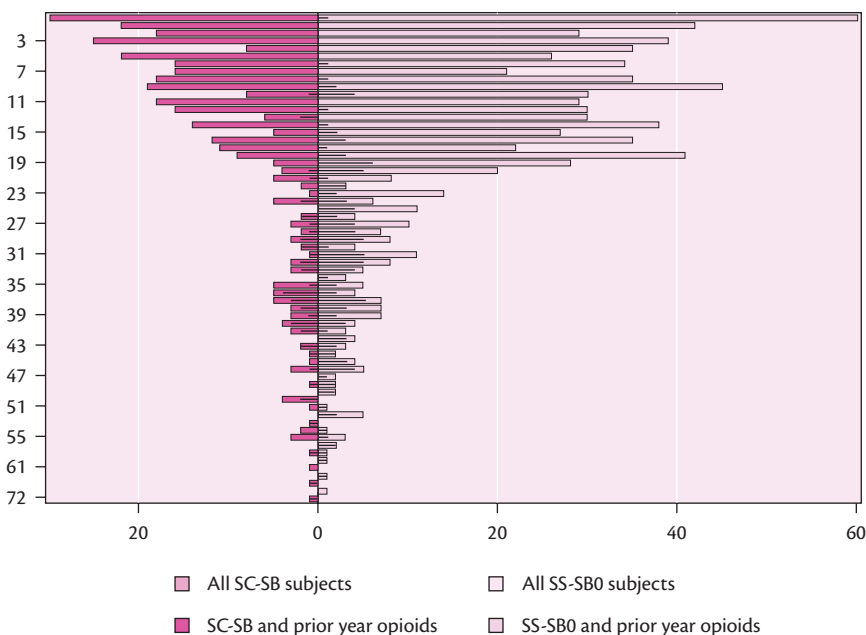

Several studies in mouse models of SCD have described sensory changes consistent with altered nociceptor function. Paw withdrawal threshold and withdrawal latency (to mechanical and thermal stimuli, respectively) and grip force were lower in homozygous and hemizygous Berkley mice, which express only human sickle haemoglobin, compared with control mice expressing human haemoglobin A consistent with deep/musculoskeletal and cutaneous hyperalgesia (Kohli et al., 2010). This mechanical hypersensitivity is further exacerbated when hypoxia is used to induce acute sickling (Hillery et al., 2011). Several research groups are working with these and similar mouse models to define unique molecular mechanisms of pain and identify potential therapeutic targets.

Preliminary human studies suggest similar sensory changes consistent with hyperalgesia in children and adults with SCD. Early studies suggested reduced pressure pain thresholds in school-age and adolescent SCD children compared to age-matched children with juvenile idiopathic arthritis, or compared to control children with asthma (Walco et al., 1990). In a recent cross-sectional study using quantitative sensory testing to thermal and mechanical stimuli in SCD paediatric patients in

baseline health ( $n = 55$ ) and race-matched controls ( $n = 57$ ), SCD patients when compared to controls had significantly lower cold pain thresholds and heat pain thresholds, but not mechanical pain thresholds (Brandow et al., 2011). Older age was associated with lower cold pain thresholds, lower heat pain thresholds, and lower mechanical pain thresholds. Further studies will be necessary to characterize the risk factors and time course for these changes in processing of nociceptive signalling in both children and young adults with SCD, and to determine their implications for analgesic management.

## Conclusion

SCD is a complex pain disorder that remains poorly understood with limited evidence base for analgesic therapies. Pain from vaso-occlusion of sickle erythrocytes can occur in multiple musculoskeletal locations, several internal viscera such as the spleen, as well as the penis. Such pain is typically intermittent in childhood, and often responds to NSAIDs and opioid analgesics similarly to acute pain in many other pain disorders. Adolescents with SCD often experience more frequent pain, and those with bone disease in spine, hips, or shoulders may experience chronic pain, which may show limited responses to opioids as in other chronic pain disorder. Many cognitive-behavioural strategies are helpful as part of multidisciplinary pain management, particularly in adolescents, who may also benefit from psychological support for coexistent mood disorders, to increase coping skills, and to support appropriate school and family functioning. Future advances are needed to further the evidence base for efficacious pharmacological and psychological therapies to ameliorate the substantial burden of pain in children and adolescents with SCD. Ultimately preventive therapies for vaso-occlusion, inflammatory and ischaemic tissue damage, and development of hyperalgesia will finally change the face of this common genetic disorder (Figure 25.1).

**Figure 25.1** Age distribution of opioid usage in the year prior to registry enrolment. Bars represent the number of individuals in each year of age, with bars on the left representing SC or SB + thal subjects, while bars on the right represent the number of subjects with SS or SB0thal. Dark bars within each group represent the number of subjects reporting chronic daily opioid usage.

### Case example

JK is a 18-year-female with homozygous sickle cell disease (SS) diagnosed at birth through the local state newborn haemoglobinopathy screening programme. Her mother noticed prominent swelling of the dorsum of left hand and fingers of her daughter associated with reduced voluntary movement and discomfort with palpation at age 18 months preceded by a mild upper respiratory infection that responded to oral ibuprofen. Several subsequent episodes involving one or both hands and feet or sometimes her lower legs occurred over the next several years and were managed at home with oral ibuprofen and oral acetaminophen/codeine. Her family would often apply warm compresses and massage her limbs to help relieve swelling and pain. At age 5 she was admitted for several days with more severe pain managed with intravenous fluids, NSAIDs, and intravenous opioids (morphine). By age 12, similar admissions began to occur once to twice per year, which were interspersed with less severe episodes once or twice a month lasting several days. She began to miss considerable amounts of school and became somewhat withdrawn and spent less time with her friends. Oral hydroxyurea was started but had little impact on her pain complaints, in part because of poor adherence. More potent intermittent oral opioids were started, and provided some initial improvement in pain relief, but subsequently poorly controlled pain necessitated a switch to daily oral methadone. A variety of adjuvant medications were tried but were found to be too sedating or had other significant side effects. A TENS unit was provided, which she found to be useful for mild to moderate pain. At age 13, her physical activity was further compromised by persistent right-sided hip pain; hip X-rays and MRI demonstrated significant avascular necrosis of her right femoral head with partial collapse.

When she was 15 years of age, her family, who were increasingly concerned with her isolation, depression, and poor school performance, requested a multidisciplinary case conference with members of the sickle cell team, physical therapy, the hospital-based school teacher, child psychology, and a representative from the local hospital-based pain team. A comprehensive management plan was developed with the concurrence of JK and her family that included a 12- to 18-month period of chronic transfusions in an attempt to ameliorate her underlying SCD, intensive physical therapy to improve conditioning and to assist with physical mobility of her hips, and individual and family psychology sessions to teach more effective communication styles and more successful active coping skills. A variety of relaxation techniques were to be taught to assist with stress management and to improve sleep hygiene. Under careful medical and psychological supervision, off-label use of duloxetine was started to improve pain control based on data from other pain disorders, and provide some antidepressant action. She was encouraged to become more active in her local church youth group, and was referred to a local African American college sorority programme that provided high school academic tutoring and role-modelling. Her frequency of hospitalization gradually decreased on this intensive supportive care programme, and she was able to be weaned to a small dose of daily opioids with further improvements in her pain characteristics, suggestive of some previous degree of opioid-induced hyperalgesia. She restarted oral hydroxyurea with an improved

clinical response. With the assistance of her volunteer tutors, she was able to graduate from high school with her class, and will be starting a reduced schedule of community college classes in preparation for a healthcare-related degree programme.

## CHAPTER 26

# Pain and gastroenterological diseases

Akshay Batra, Amanda Bevan and R. Mark Beattie

### Summary

Pain is a common complaint in children with gastrointestinal tract pathology and it has significant consequences for patients' quality of life. A thorough evaluation should be performed to determine the cause and severity. Understanding the pathophysiology of pain in various conditions is key to effective management. This chapter outlines the aetiology and general principles of the management of pain in gastrointestinal disease. The specific management of common gastrointestinal conditions associated with pain, e.g. inflammatory bowel disease, gastro-oesophageal reflux disease, pancreatitis, and gut dysmotility disorders are discussed.

### Introduction

Pain is an important and common symptom of gastrointestinal disease. It can be the first indication of a new pathology, or it can signify a change in a known condition. The recognition of the pain pattern and its significance is crucial to the early diagnosis and treatment. The relief of pain is frequently of diagnostic importance and is often the best indicator of successful treatment. This chapter will focus on the various gastrointestinal disorders causing pain and their management with special emphasis on conditions causing acute debilitating pain. Recurrent abdominal pain is reviewed by Schurman et al. (Chapter 29, this volume).

### Innervation of the gastrointestinal tract

The lining of the gastrointestinal tract is the largest vulnerable surface that faces the external environment. Pain perception in the gastrointestinal tract is mediated via a complex pathway of enteric, autonomic, and central nervous system (CNS) structures (Knowles and Aziz, 2009).

#### Enteric nervous system

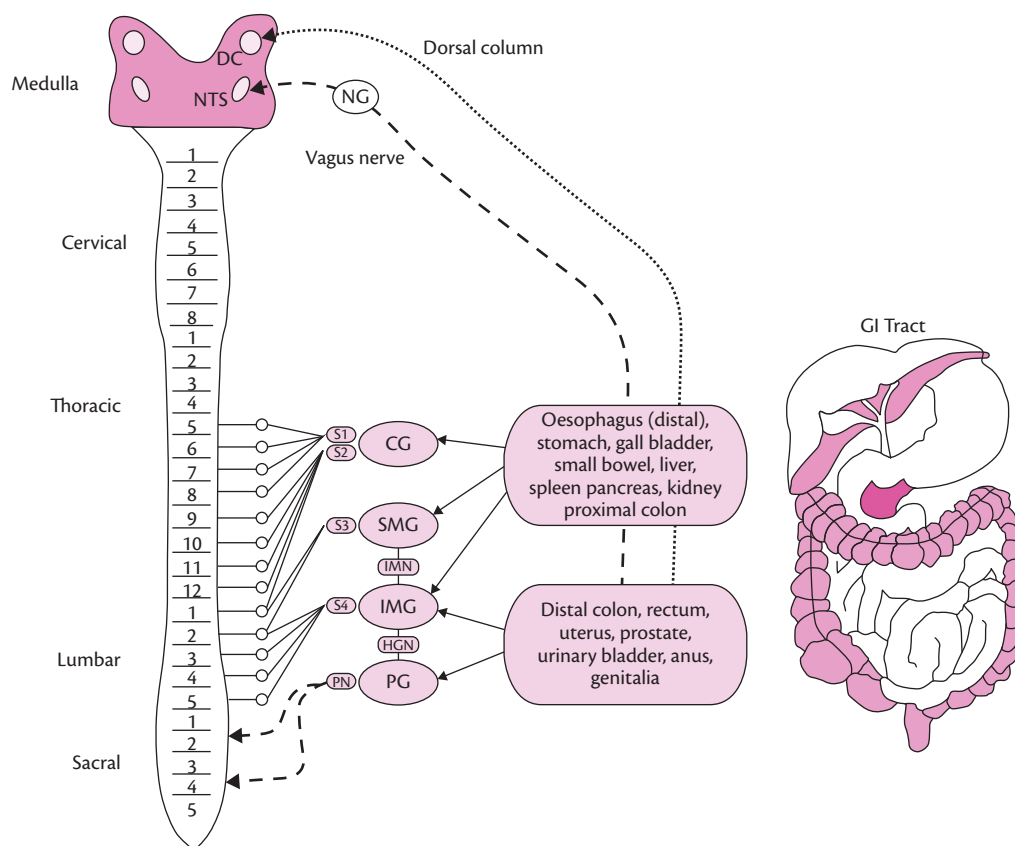

The enteric nervous system provides the intrinsic innervation to the gut. It is composed of Auerbach's and Meissner's plexuses. Auerbach's plexus is a myenteric plexus which lies between the longitudinal and circular muscle layers. Its role is mainly to control the contractions of the smooth muscle in the bowel. The submucosal Meissner's plexus lies below the mucosal layer and performs a predominantly sensory function in obtaining information about the luminal contents.

Three broad classes of primary afferent neurons associated with the gut are:

- ♦ Intrinsic primary afferent neurons (IPANs), with cell bodies and connections in the gut wall, either in the myenteric plexus or in the submucous plexus, and processes extending to muscularis mucosa. They are the primary sensors and regulators of the enteric nervous system (Gershon et al., 2005).
- ♦ Extrinsic primary afferent neurons, with cell bodies in vagal and dorsal root (spinal) ganglia, carry information about the state of the gastrointestinal tract to the CNS. They appear to monitor all aspects of gut function, and also carry nociceptive information via thinly myelinated A $\delta$  and unmyelinated C fibres (Sengupta, 1994; Sikander and Dickenson, 2012). Both the submucosal and muscular nerve plexus respond to multiple stimuli and transmit pain to the CNS.
- ♦ Intestino-fugal neurons, with cell bodies in the gut and projections to neurons outside the gut wall.

Visceral sensory nerves follow three main anatomical pathways from the gastrointestinal tract to the CNS: the vagal, splanchnic, and pelvic nerves (Kirkup et al., 2001; Sikandar and Dickenson, 2012) (Figure 26.1). The splanchnic afferent neurons transmit pain sensation, whereas the parasympathetic afferent fibres transmit physiological information and non-noxious sensation (Goyal et al., 1996). The cell bodies of primary visceral afferent neurons are contained in the nodose ganglia (vagal afferents) and dorsal root ganglia (spinal afferents). The central terminals of vagal sensory neurons are in the brainstem, whereas the central terminals of spinal visceral afferent neurons are organized diffusely over several spinal segments. The vagal afferents do not directly participate in pain signalling but can indirectly modify spinal pain processing.

The autonomic nervous system, by way of the sympathetic and parasympathetic systems, also controls the secretory and muscular functions of the gut. Parasympathetic efferent fibres run in the vagus and sacral nerves, and exert an excitatory effect on the enteric neurons. The sympathetic efferent fibres inhibit gastrointestinal activity. The enteric nervous system though functioning independently interacts with the CNS allowing bidirectional communication. As a result the brain can integrate information from the gastrointestinal tract and respond appropriately. This is especially true for stimuli

**Figure 26.1** Schematic of gastrointestinal tract innervation. Visceral afferents innervating organs in thoracic and abdominal cavities travel either along the vagus nerve with cell bodies in the nodose ganglion (NG) and central terminals in the nucleus tractus solitarius (NTS), or along the dorsal column pathway (dotted line) with cell bodies in dorsal column nuclei (DC) in the brainstem. Other afferents innervating the same organs have terminals in the spinal cord, before passing through pre- and/or paravertebral ganglia en route with cell bodies in dorsal root ganglia (not illustrated). Straight lined pathways indicate sympathetic innervation and hyphenated pathways indicate parasympathetic innervation. Prevertebral ganglia, CG: coeliac ganglion; SMG: superior mesenteric ganglion; IMG: inferior mesenteric ganglion; PG: pelvic ganglion. Nerves, S1, S2, S3, S4: greater, less, and lumbar splanchnic nerves, respectively; IMN: intermesenteric nerve; HGN: hypogastric nerve; PN: pelvic nerve. Republished from Sikandar, Shafaq and Dickenson, Anthony H, Visceral pain: the ins and outs, the ups and downs, *Current Opinion in Supportive and Palliative Care*, Volume 6, Issue 1, pp. 17–26, Copyright © 2012 Lippincott Williams & Wilkins, Inc, <http://journals.lww.com/co-supportiveandpalliativecare/pages/default.aspx>.

like hunger, satiety, and defecation (Blackshaw and Gebhart, 2002) thus providing a degree of conscious control over these functions; however, we are normally unaware of the complex signalling events which continuously occur within our internal organs.

Various neurotransmitters within the enteric nervous system take part in relaying this information. The excitatory neurotransmitters include acetylcholine, and substance P and inhibitory transmitters include adenosine triphosphate, vasoactive intestinal peptide, and nitric oxide. Serotonin, a monoamine neurotransmitter, plays a key role in the initiation of peristaltic and secretory reflexes, and in modulation of visceral sensations.

## Neural pathways for pain

### Peripheral visceral mechanisms

Sensory nerve endings (i.e. visceral nociceptors), in the mucosal or muscular layer are activated by a range of stimuli, such as mucosal and serosal inflammation, traction on the mesentery, rapid luminal distention, ischaemia, and forceful smooth muscle contraction. *Mucosal* afferents appear as bare endings in the lamina propria of intestinal villi and respond to luminal and local chemical stimulation of the mucosal surface. This may involve (Berthoud et al. 1995; Gebhart, 2000):

- ♦ Direct activation or mucosal damage due to excess hydrogen ions in conditions such as oesophagitis.
- ♦ Activation by pro-inflammatory neurotransmitters (e.g. histamine and substance P) that increase excitability of the receptors (i.e. peripheral sensitization) in inflammatory bowel disease.
- ♦ Direct involvement of the nerve in the inflammatory process (i.e. neuritis) as is seen in transmural inflammation with Crohn's disease.

*Muscular* afferents respond to mechanical stimuli, especially distention, and consist of specialized terminals which surround myenteric ganglia termed intraganglionic laminar endings (ILEs; Lynn et al., 2003). Pain can result from pathological conditions in which distention is beyond the tolerance threshold of the organ (e.g. acute intestinal obstruction); or be associated with a lower tolerance to distention, which is a proposed mechanism in functional abdominal pain. In conditions like chronic pseudo-obstruction there is a combination of the two factors: perception of distention is altered secondary to neuropathy, and there is also excessive distention secondary to myopathic changes (Gebhart, 2000). In addition, a subgroup of visceral afferent fibres are mechanically insensitive, so-called mechanically insensitive afferents (MIAs) or 'silent' nociceptors, but which acquire

spontaneous activity and mechanosensitivity after tissue insults such as inflammation or mechanical trauma (Feng et al., 2012).

As the density of visceral sensory innervation is relatively sparse and there is marked divergence of visceral input into the spinal cord, visceral pain tends to be diffuse and poorly localized (Sikandar and Dickenson, 2012).

### Peritoneal pain

Pain may also be produced by chemical stimulation, ischaemia, inflammation, or stretching of the parietal peritoneum, which is innervated by branches from somatic efferent and afferent nerves that also supply the muscles and skin of the overlying body wall. The parietal peritoneum lining the anterior abdominal wall is supplied by lower six thoracic and first lumbar nerves; and in the pelvis is mainly supplied by the obturator nerve, which is a branch of the lumbar plexus. Parietal pain is sharp, severe, and very well localized, and experienced in conditions such as peritonitis, appendicitis, and pancreatitis.

### Central processing of visceral pain

In the spinal cord, visceral afferent input converges with somatic afferent input, resulting in referred visceral pain. In addition, ongoing activity due to sensitization of peripheral afferents, recruitment of MIAs, and interactions with intestinal immune cells (mast cells, macrophages, and lymphocytes) can result in sensitization of central nociceptive processing. Visceral pain sensitivity can also be modulated by descending pathways, particularly from the rostro-ventral medulla, and this may contribute to associations between of anxiety, stress, and functional abdominal pain (Feng et al., 2012; Sikander and Dickenson, 2012).

### Postnatal development of visceral pain mechanisms

Age-related changes in the distribution or function of gastrointestinal afferents have not been directly evaluated throughout postnatal development (Christianson et al. 2009). However, it is clear that visceral mechanisms are functional in neonates and infants, as referred visceral hyperalgesia can be measured by changes in abdominal skin reflexes (Andrews et al., 2002), and repeated noxious stimuli in early life may contribute to persistent hyperalgesia (Anand et al., 2004).

### Assessment

Assessment of a child with abdominal pain requires a careful and detailed history and examination. The main aim is to locate the cause of the pain, where possible (Table 26.1), and determine its severity and resulting disability. The history should focus on the site and radiation, type and duration of pain, aggravating and relieving factors, and its intensity. Pain needs to be interpreted in the context of any known pathology, potential new pathology, and the impact of pain on functioning. Examination includes overall impression (e.g. ill/well, malnourished, pale) and assessment of the systemic impact of pain with regard to changes in heart rate and blood pressure. Abdominal examination may help identify the site of pain by associated features including tenderness, guarding, and rebound, and identify any other associated factors such as organomegaly or palpable masses.

### Pain assessment

Pain assessment is discussed elsewhere in this text, but examples of use in children with abdominal pain include:

**Table 26.1** Classification of conditions presenting with abdominal pain

Gastrointestinal conditions presenting with abdominal pain	
Diseases affecting the mucosal lining	Esophagitis:
	◆ Reflux esophagitis
	◆ Eosinophilic esophagitis
	◆ Infections of oesophagus
	Gastritis
	Peptic ulcer disease
	Duodenal ulcers
	Inflammatory bowel disease
	Crohn's disease
	Ulcerative colitis
	Indeterminate colitis
	Eosinophilic gastroenteritis
	Infective enterocolitis
Diseases affecting the smooth muscles	Acute intestinal obstruction
	Chronic intestinal pseudo-obstruction
	Functional recurrent abdominal pain
	Distal intestinal obstruction syndrome (DIOS)
	Constipation
Diseases involving the parietal peritoneum	Pancreatitis
	Appendicitis
	Peritonitis
Non-gastrointestinal causes of abdominal pain	
	Lower respiratory tract infection
	Urinary tract infection
	Cholecystitis
	Henoch–Schönlein purpura
	Sickle cell crisis
	Testicular torsion
	Pelvic inflammatory disease
	Pyelonephritis
	Diabetic ketoacidosis
	Haemolytic uremic syndrome

- ◆ Self-report tools have been used to quantify pain intensity with good agreement between the Wong–Baker Faces Scale and visual analogue scale in children (8–17 years) presenting to the emergency department with acute pain, of whom 19% had abdominal pain (Garra et al. 2010).
- ◆ Multidimensional Measure for Recurrent Abdominal Pain (MM-RAP) also quantifies non-pain symptoms associated with bowel disease (nausea or vomiting, heartburn, diarrhoea, constipation, flatulence, loss of appetite, bloating, sour taste, bad breath, sleep problems, and problems with ingestion of milk) and disability. It is best used in an outpatient setting

for children with long standing recurrent abdominal pain (Malaty et al., 2005; see also Schurman et al., Chapter 29, this volume).

## Inflammatory bowel disease

Inflammatory bowel disease (IBD) is a chronic relapsing illness affecting the gastrointestinal system that includes:

- ♦ Crohn's disease (CD) is a chronic, idiopathic transmural inflammation which can affect one or several segments anywhere in the digestive tract. CD is also characterized by the type of disease into inflammatory, fistulating, and structuring disease.
- ♦ Ulcerative colitis (UC) is a chronic idiopathic mucosal inflammation limited to the colon. It extends from the rectum continuously over a variable length of the colon from the distal to the proximal end.
- ♦ Indeterminate colitis (IC) is reserved for cases of colitis in which findings are not sufficient to allow differentiation between CD and UC. The disease is characterized based on its severity ranging from mild to severe and its distribution in the gastrointestinal tract.

The aetiologies of both UC and CD remain unknown, but a response to environmental triggers like infection, drugs, or chemical agents in genetically susceptible individuals is the current consensus. Approximately 20% to 30% of patients with IBD present before the age of 18 years (Heyman et al., 2005; Sawczenko et al., 2001; Vind et al., 2006).

## Clinical presentation

The common presenting features are abdominal pain, diarrhoea, and weight loss. Other features can include rectal bleeding, lethargy, anaemia, anal fissures or abscesses, mouth ulcers, or arthritis. Abdominal pain is a presenting feature in up to 72% of children with IBD (Sawczenko and Sandhu, 2003), and is the most debilitating symptom. Evaluation of pain is an important part of assessing disease severity and is a component of several disease activity indices. Pain may be due to ongoing intestinal inflammation or secondary to complications such as strictures, subacute bowel obstruction and abscesses seen in CD, or toxic megacolon in UC. Other conditions causing pain in IBD include gall stones, renal calculi, and chronic pancreatitis, and management principally involves treating the underlying pathology. Perianal disease can result in localized severe and difficult to control pain.

About 20% to 30% of adults with IBD continue to have pain without evidence of active inflammation, obstruction, or other biologically defined abnormalities (Bielefeldt et al., 2009; Colombel et al., 2010). Similarly, ongoing pain in children with IBD could be due to persistent sensitization in the gastrointestinal tract following inflammation and high rates of irritable bowel syndrome. Psychological and cognitive factors may also influence pain experience (Docherty et al., 2011).

## Management

In patients with active inflammation, analgesics alone are generally less effective until the underlying cause is resolved. Inflammation or stricture formation requiring more intense medical or even surgical therapy likely explain why significant pain requiring analgesic therapy is a negative prognostic indicator (Lichtenstein et al., 2006).

Inflammation can be controlled by the following (Sandhu et al., 2010):

- ♦ *Exclusive enteral nutrition* is an effective treatment for children with Crohn's disease and induces remission in 60% to 80% of the cases (Fell et al., 2000). Polymeric or elemental diets are equally effective. Duration of exclusive enteral nutrition is usually 6 weeks, and depending on patient symptoms, food may be cautiously reintroduced whilst weaning the enteral feed over 1 to 3 weeks.
- ♦ *Corticosteroids* are potent anti-inflammatory agents for moderate to severe relapses of both UC and CD. They act through inhibition of several inflammatory pathways—suppressing interleukin transcription, induction of IκB that stabilizes the NFκB complex, suppression of arachidonic acid metabolism, and stimulation of apoptosis of lymphocytes within the lamina propria of the gut (Steinhart et al., 2001). Commonly used steroids are prednisolone in the dose of 2 mg/kg/day (max 40mg/day). Side effects include acne, moon face, sleep and mood disturbance, dyspepsia, or glucose intolerance. Effects associated with prolonged use include osteoporosis, osteonecrosis of the femoral head, myopathy, impaired growth, and susceptibility to infection.
- ♦ *Monoclonal antibody therapy* such as infliximab, a chimeric anti-tumour necrosis factor monoclonal antibody with potent anti-inflammatory effects. It was initially developed for use in patients with moderate to severe luminal or fistulizing CD who are refractory to standard medical therapy, but is now being used more widely. Although used predominantly to treat CD, recent data suggest that infliximab also may have a role in the management of UC (Lawson et al., 2006).

Surgery, such as abscess drainage or fistulotomy, may be required for complications (Sandhu, 2010).

## Pain management in inflammatory bowel disease

*Non-steroidal anti-inflammatory drugs* (NSAIDs) act by inhibiting the production of prostaglandins by cyclo-oxygenase (COX) enzymes (see Anderson, Chapter 43, this volume). The effect is mediated through inhibition of both the inducible form of the enzyme, COX-2, and the constitutively produced COX-1 enzyme, resulting in reduced prostaglandin production, which may also result in gastrointestinal side effects. NSAIDs have been linked in some reports to a higher likelihood of disease exacerbation. A 20% to 30% increase in risk of flare-ups was seen with use of NSAIDs in IBD, and all NSAID-treated patients experiencing a flare were able to re-attain remission simply by stopping the NSAID (Takeuchi et al., 2006). Even though controlled trials using NSAIDs in IBD are lacking, a large study including 500 adults failed to find any association between disease relapse and use of NSAIDs (Bernstein et al., 2010). NSAIDs can probably be safely used in children with IBD, particularly in the short term, but should be withdrawn if gastrointestinal side effects are seen or the disease flares and the NSAIDs are felt to be a factor. NSAID-induced enterocolitis is seen rarely (Geramizadeh et al., 2009).

*Hyoscine butylbromide* blocks the effects of acetylcholine at muscarinic receptors in the periphery, and has no central effects (unlike hyoscine hydrobromide) as it does not cross the

blood–brain barrier. Hyoscine butylbromide has an inhibitory effect on smooth muscle and reduces gastrointestinal motility. As only 2% to 8% of an oral dose is absorbed, effects are mainly related to topical actions in the proximal gut, with no effect on the jejunum. Intravenous administration inhibits motility throughout the bowel (Dollery, 1998).

*Opioids* are mainly used for the management of acute pain in IBD, and have a well-defined role in the management of postoperative pain in children with IBD requiring surgery. The use in acute cases of disease flare-up is controversial, as opioids can induce significant adverse effects on gastrointestinal function and gut motility. Even at low doses, morphine decreases gastric motility, and may prolong gastric emptying time by up to 12 h as the tone of the antral portion of the stomach and the first part of the duodenum is increased. Propulsive contractions are reduced in the duodenum and colon, and colonic muscle tone is increased (the ileum is less affected), leading to constipation which can be severe (Brunton et al., 2011). Opioids also exert complex effects on the immune system via centrally mediated and direct cellular effects; and immunomodulatory effects are an area of active research in inflammatory bowel disease (Mani and Moore, 2009; Philippe et al., 2006; Zagon and McLaughlin, 2011).

In children presenting with an acute flare of IBD, opioids should be used with extreme caution and close monitoring for signs of toxic megacolon (e.g. tachycardia, fall in blood pressure, and increasing abdominal distension). The N-methyl-D-aspartate antagonist ketamine has been shown to reduce acute visceral hyperalgesia in adult volunteers (Willert et al., 2004), but efficacy and potential long-term side-effects have not been evaluated in children with gastroenterological disease.

Long-term opioid use in children with IBD is discouraged, and has been associated with poorer outcomes in adults (Cross et al., 2005). The TREAT registry prospectively followed over 6000 patients with Crohn's disease, half of whom received infliximab. Chronic narcotic analgesics use was associated with an increased risk of infection (odds ratio, 2.38; 95% confidence interval 1.56–3.63; Lichtenstein et al., 2006). However, the increased complications associated with opioid use may be an indicator of more severe IBD, as adults treated with opiates were more likely to have increased disease activity, and were almost twice as likely to require surgical intervention (Cross et al., 2005).

## Gastro-oesophageal reflux disease

Gastro-oesophageal reflux results in passage of the gastric juices and acid into the oesophagus. It is a normal physiological process occurring several times a day, particularly in the post-prandial period. Frequent episodes of transient relaxation of the lower oesophageal sphincter in response to gastric distention and vagal stimulation normally last for 10 to 30 sec, allowing retrograde flow of the stomach contents. Infants develop symptoms, such as vomiting, irritability and coughing after feeds if there are prolonged or excessively frequent relaxations of the sphincter (Box 26.1). Symptoms resolve by 6 months of age in 60% of children with reflux, and by 1 year in approximately 90% of infants (Martin et al., 2002).

A higher frequency of transient lower oesophageal sphincter relaxation and prolonged duration of oesophageal acid exposure may result in pathological gastro-oesophageal reflux disease (GORD), with associated complications such as erosive oesophagitis, respiratory complications, or weight loss. When symptoms

### Box 26.1 Symptoms and signs of gastro-oesophageal reflux disease (GORD)

#### Symptoms

- ◆ Recurrent regurgitation with/without vomiting
- ◆ Weight loss or poor weight gain
- ◆ Irritability
- ◆ Ruminative behaviour
- ◆ Heartburn or chest pain
- ◆ Dysphagia, odynophagia
- ◆ Wheezing
- ◆ Stridor
- ◆ Cough
- ◆ Feeding refusal.

#### Signs

- ◆ Esophagitis
- ◆ Oesophageal stricture
- ◆ Barrett oesophagus
- ◆ Laryngeal/pharyngeal inflammation
- ◆ Recurrent pneumonia
- ◆ Anaemia
- ◆ Dental erosion
- ◆ Dystonic neck posturing (Sandifer syndrome)
- ◆ Apnoea spells.

persist beyond 18 months of age, there is higher likelihood of a pathological cause (Gold, 2004). Alterations in several protective mechanisms allow physiological reflux to become GORD: delay in gastric emptying, poor clearance of refluxed gastric juices from the oesophagus, or abnormal position of the lower oesophageal sphincter in the thoracic cavity (Cosgrove and Dodge, 1998).

## Diagnosis

The diagnosis of GORD is predominantly based on history and examination or on response to treatment. It is important to differentiate this condition from foregut dysmotility, in which infants present with symptoms of vomiting and discomfort after feeds, but the typical features of arching, excess salivation, and feed refusal are absent. Infants with dysmotility have associated intermittent abdominal distension and altered bowel habits. A pH study can quantify oesophageal acid exposure by the number and duration of reflux episodes (pH <4.0) and the percentage of the entire record that oesophageal pH is less than 4.0. Although this test has established normal ranges, it is likely that a continuum between physiological GORD and pathological GORD exists, and the severity of pathologic acid reflux does not consistently correlate with symptom severity or demonstrable complications. Oesophageal pH monitoring can also help determine if a temporal association exists between episodes of reflux and atypical symptoms (chronic cough, stridor, wheezing, apnoea, irritability, or opisthotonic posturing) and evaluate the efficacy of antisecretory therapy (Colletti et al., 1995).

## Management

Management of GORD in children is based on its severity, the degree of functional impairment, and presence or absence of complications. The goals for treatment are to relieve symptoms, heal oesophagitis if present, maintain remission of symptoms, and manage or prevent complications. Treatment options include:

- ♦ *Dietary management* by modifying infant feeding techniques and changing formula composition with addition of thickening agents. In one study, this improved vomiting and irritability in approximately one-quarter of infants with GORD symptoms (Shalaby et al., 2003). As symptoms of milk protein allergy can overlap those of GORD, a 2-week trial of hypoallergenic formula can be considered (Rudolph et al., 2001).
- ♦ *Pharmacological therapy* suppresses gastric acid production by histamine H<sub>2</sub> receptor blockers such as ranitidine, or proton pump inhibitors (PPIs) such as omeprazole, which have been shown to be more effective in reducing gastric acidity (van der Pol et al., 2011). Omeprazole given for 12 weeks resolved moderate-to-severe GORD symptoms in all but 7% of paediatric patients aged 1 to 16 years (Hassal et al., 2000). There is some conflicting data on whether histological findings as well as symptoms are improved (van der Pol et al., 2011). PPIs are safe and well tolerated in children of all ages (Faure et al., 2001; Hassal et al., 2000), with adverse events (headache, constipation, diarrhoea, and abdominal pain) in less than 5% of patients.
- ♦ *Surgery* may be indicated for failed medical therapy or symptom recurrence. Fundoplication is performed with consideration of a pyloroplasty if there is delayed gastric emptying, and/or a gastrotomy if there are feeding problems (Granderath et al., 2002). Postoperative analgesic requirements did not differ in a randomized trial of laparoscopic versus open fundoplication (McHoney et al., 2011), and a meta-analysis reported reduced postoperative complications, faster recovery, but an increased risk of reoperation following laparoscopic versus open surgery (Peters et al., 2009).

## Pancreatitis

Pancreatitis is an inflammatory process associated with autodigestion of the gland by its enzymes, and can be acute or chronic. Although relatively rare in children, it is associated with high morbidity, but mortality rates are lower than in adult populations (Mekitarian et al., 2012). In a series of 279 paediatric cases, causes of pancreatitis in children included trauma (36%), systemic disease (22%), metabolic (6%), biliary (5%), drugs (3%), and viral illness (2%); but 25% were deemed idiopathic (Nydegger et al., 2007) (Box 26.2).

## Pathophysiology

Mechanisms of pain associated with chronic pancreatitis may include (Tsiotou 2000):

- ♦ Increased pressure and tension within the gland due to blockage of the ducts. This hypothesis prompted development of techniques to endoscopically decompress the gland.
- ♦ Mechanical blockage of surrounding structures such as the duodenum secondary to enlargement of the gland, resulting in partial obstruction and pain.
- ♦ Local nerve injury and neuropathic pain.

### Box 26.2 Aetiology of acute and chronic pancreatitis in children

#### Acute pancreatitis

- ♦ Infectious:
  - ♦ Coxsackie B virus
  - ♦ Epstein–Barr Virus
  - ♦ Hepatitis
  - ♦ Measles
  - ♦ Rubella
  - ♦ Malaria
  - ♦ Mumps
  - ♦ Mycoplasma
  - ♦ Influenza A & B.
- ♦ Hereditary pancreatitis.
- ♦ Drugs and toxins:
  - ♦ Alcohol
  - ♦ Azathioprine/6-mercaptopurine
  - ♦ Corticosteroids
  - ♦ Valproic acid
  - ♦ Sulfonamides
  - ♦ Erythromycin
  - ♦ Enalapril
  - ♦ L-asparaginase
  - ♦ Vincristine.
- ♦ Trauma.
- ♦ Obstructive:
  - ♦ Pancreatic duct abnormality
  - ♦ Biliary tract malformations
  - ♦ Sphincter of oddi dysfunction
  - ♦ Pancreas divisum
  - ♦ Choledocal cyst
  - ♦ Duplication cyst
  - ♦ Complication of endoscopic retrograde cholangio-pancreatography (ERCP)
  - ♦ Tumours.
- ♦ Systemic disease:
  - ♦ Alpha 1 antitrypsin deficiency
  - ♦ Cystic fibrosis
  - ♦ Haemochromatosis
  - ♦ Haemolytic uraemic syndrome
  - ♦ Malnutrition
  - ♦ Hyperparathyroidism
  - ♦ Vasculitis syndromes

**Box 26.2** (Continued)

- ◆ Hypercalcaemia
- ◆ Hyperlipidaemia
- ◆ Sepsis/shock.

**Chronic pancreatitis**

- ◆ Hereditary pancreatitis
- ◆ Idiopathic fibrosing pancreatitis
- ◆ Cystic fibrosis
- ◆ Hyperlipidaemia/hypercalcaemia
- ◆ Trauma
- ◆ Congenital anomalies
- ◆ Wilson's disease.

The innervation of the pancreas is complex, involving both somatic–visceral and autonomic nerves. Painful stimuli, such as pressure, acid or chemicals released by cellular necrosis activate receptors on somatic–visceral nociceptive neurons in the pancreatic bed. The signal passes cephalad along both unmyelinated C-fibres and small myelinated A $\delta$  fibres, through the celiac plexus via the left and right greater splanchnic nerves, and through the sympathetic trunk ganglia to the cell body in the dorsal root ganglia, to synapse in the spinal cord at levels T5 to T9. Sensory neurons from the back and epigastric rectus abdominus muscles are also found at this level, resulting in pain of pancreatitis being referred to the back and/or epigastric region.

**Clinical presentation**

Acute pancreatitis presents with vomiting and abdominal pain, which is characteristically a sharp, steady pain of sudden onset, aggravated by eating and improved by drawing the knees up to the chest. The pain is generally epigastric, but may be experienced in the middle or even lower abdomen, or referred to the back. Physical signs include fever and tachycardia. White cell count and inflammatory markers may be increased. Serum amylase is usually elevated and starts to subside by 3 to 5 days, but the degree of elevation does not correlate directly with severity of disease severity, and normal levels do not rule out the diagnosis (Lautz et al., 2011). Serum lipase may also remain elevated for 1 to 2 weeks. Ultrasound imaging can demonstrate an enlarged, oedematous pancreas, a dilated main pancreatic duct indicates obstruction, and calcifications are often seen in older children with recurrent pancreatitis.

Most episodes of acute pancreatitis in children are isolated and self-limited, but patients with recurrent episodes may progress to chronicity. Recurrent acute pancreatitis is commonly associated with congenital malformations of pancreatico-biliary tract, gallstones, cystic fibrosis, and familial pancreatitis (Nydegger et al., 2006). Familial pancreatitis has been associated with mutations in: cationic trypsinogen gene (e.g. *PRSS1*) which enhances trypsin activation; *SPINK1* (serine protease inhibitor Kazal type 1) gene resulting in an abnormal pancreatic secretory trypsin inhibitor; and the *CFTR* (cystic fibrosis transmembrane conductance regulator) gene, which reduces the pancreatic fluid secretion capacity (Nydegger et al., 2006).

**Management**

Management of children with pancreatitis requires analgesia, fluid replacement, nutritional support, and treatment of any initiating cause (Table 26.2) or associated complications (Mekitarian et al., 2012):

- ◆ **Analgesia:** providing adequate analgesia is an important part of management of acute pancreatitis, and opioids are commonly used. There is no definitive human study to support the widespread belief that morphine exacerbates pancreatitis by stimulating the sphincter of Oddi to contract (Toouli et al., 2002), and no studies suggest that use of morphine is contraindicated in acute pancreatitis (Thompson 2001). Other drugs which may be beneficial include acetaminophen and non-steroidal anti-inflammatory agents. Drugs for neuropathic pain may be considered in chronic cases (see Rastogi and Campbell, Chapter 48, this volume). Pregabalin reduces acute acid-induced hyperalgesia in adult volunteers (Chua et al., 2012), but there is currently no data to confirm efficacy or inform appropriate patient selection in children who may have visceral hyperalgesia.
- ◆ **Pancreatic rest:** in acute cases, preventing oral intake 'rests' the pancreas and provides symptomatic relief (Lordan et al., 2009). Without any food being presented to the gut, secretions from the gastric glands are reduced, and reduced enzyme release by the pancreas decreases both autodigestion and pancreatic distension. Nutrition is critically important in patients with pancreatitis and an early positive nitrogen balance improves survival rates in adults (Meier et al., 2006). In adult studies, placement of a nasojunal tube for feeding has been shown to be as effective as parental nutrition, with reduced infectious complications (Kalfarentzos et al., 1997), and both assist in controlling pain (Raimondo et al., 2005). In patients with chronic pancreatitis there is limited research on the benefit of restricted diets, and it would be prudent to provide a well-balanced nutritionally complete diet (Shea et al., 2000; Toouli et al., 2002).
- ◆ **Somatostatin analogues:** octreotide has been used in adults for management of acute pain in pancreatitis as it suppresses cholecystokinin and pancreatic secretions (Uhl et al., 1999), and some but not all data suggests improved outcome (Beechey Newman 1993; Heikenen et al., 2002). Paediatric data is limited to case reports, and octreotide is not routinely used in children with acute pancreatitis, although some benefit has been shown for the

**Table 26.2** Groups of medication used in management of constipation

Class of drug	Example	Mechanism of action
Osmotic laxatives	Lactulose, macrogols, magnesium sulphate, phosphate enema	Draws and retain water in large bowel by osmosis
Stimulant laxatives	Anthraquinones, e.g. senna Bisacodyl, picosulphate	Increase intestinal motility
Lubricants/softeners	Arachis oil, liquid paraffin, docusate	Softens impacted stool
Bulking agents	Fibre, bran, isphagula, methylcellulose	Increase faecal mass and improves peristalsis
Prokinetics	Erythromycin	Improves transit by increasing peristalsis

management of complications, such as ascites and pseudocysts. (Bosman-Vermeeren et al., 1996; Rushforth et al., 1993).

- ♦ Administration of oral pancreatic enzymes may reduce pain via negative feedback inhibition to the pancreas, with some benefit shown in adults (Layer et al., 1990), but data in children is lacking.
- ♦ Antioxidant therapy has been suggested for chronic pancreatitis in adults (Bhardwaj et al., 2004), but there is conflicting data about efficacy, and further research is needed (Gachago et al., 2008).
- ♦ Antibiotics may prevent secondary bacterial infections, limit complications, and improve outcome; however, they are best reserved for severe cases, especially where pancreatic necrosis is present (Sainio et al., 1995).
- ♦ Surgical intervention is rarely required in management of pancreatitis except in cases of congenital malformations or management of complications such as drainage of pseudocysts.

## Constipation

Constipation is a very common (5–30%) cause of abdominal pain in children (van den berg et al., 2006). Most children do not have an underlying cause and the ROME III criteria for diagnosis of functional constipation include presence of two or more of the following for more than 1 month (Rasquin et al., 2006):

- ♦ Two or fewer defecations per week.
- ♦ At least one episode/week of incontinence after the acquisition of toileting skills.
- ♦ History of excessive stool retention.
- ♦ History of painful or hard bowel movements.
- ♦ Presence of a large faecal mass in the rectum.
- ♦ History of large-diameter stools which may obstruct the toilet.

History and clinical examination aim to assess the severity of symptoms and resulting functional impairment. Symptoms and signs that are suggestive of underlying pathology (Box 26.3) should be sought to ensure diagnosis or exclusion of organic conditions.

## Management

The UK National Institute for Health and Clinical Excellence (NICE) produced a clinical guideline 'CG99 Constipation in children and young people: Diagnosis and management of idiopathic childhood constipation in primary and secondary care' in May 2010 (<<http://www.nice.org.uk/cg99>>). The management of chronic functional constipation often requires a multidisciplinary approach, based on the following principles:

- ♦ Explanation of normal bowel function aids the family's understanding and improves compliance. Parents and children should be reassured that constipation is common and responds well to treatment.
- ♦ High-fibre diet is recommended along with adequate fluid intake because it adds bulk to the stool.
- ♦ Regular exercise promotes peristalsis and helps bowel transit.
- ♦ Regular toileting is a crucial part of the management to encourage regular emptying of the rectum.
- ♦ Behavioural advice and reward schemes (star charts) are helpful to gain child's trust in the management. Rewards can be given

### Box 26.3 Symptoms and signs suggestive of underlying pathology in children with constipation

- ♦ Constipation reported from birth or first few weeks of life.
- ♦ Failure to pass meconium/delay (more than 48 h) in a term baby.
- ♦ Infrequent/very large (ribbon) stools.
- ♦ Faltering growth.
- ♦ Previously known or undiagnosed weakness in legs/locomotor delay.
- ♦ Abdominal distension with vomiting.
- ♦ Perianal inspection—abnormal appearance/patency/position of anus, anteriorly placed anus or absent anal wink, fissures, fistulae, bruising, tight or patulous anus.
- ♦ Gross abdominal distension, palpable faecal mass (in at least half of these patients).
- ♦ Spine and gluteal examination—asymmetry of gluteal muscles, scoliosis, evidence of sacral agenesis, overlying skin over sacral region with discoloration, naevi, sinus, hairy patch, lipoma or central pit.
- ♦ Deformity in lower limbs such as talipes.
- ♦ Abnormal neuromuscular signs unexplained by any existing condition, such as cerebral palsy.
- ♦ Abnormal tendon reflexes.

for compliance (sitting on the toilet) at first and then for success (opening bowel in the toilet).

- ♦ Drug treatment: laxatives are used in the management of acute as well as chronic constipation. As abdominal pain in these children is principally due to faecal impaction it is poorly responsive to analgesics.
- ♦ Disimpaction of stools can reduce pain (Poenaru et al., 1997). Senna or polyethylene glycol can be used as sole agents in high doses. In severe cases, sodium picosulphate (liquid or sachets) may be required. Rectal medications (suppositories, enemas) are used if all oral medications have failed. Manual evacuation of the bowel under anaesthesia is rarely considered, and only if oral and rectal treatments fail.
- ♦ Laxatives are often needed for prolonged maintenance therapy, but need to be closely monitored, weaned only after a sustained period of normal bowel actions with no soiling, and used in conjunction with other supportive strategies. Polyethylene glycol (Movicol®) is widely used. Senokot® given in the evening, at reasonable doses, is effective. The choice of agent depends on local preference as well as individual patient circumstances (Table 26.2). Young children should remain on laxatives until toilet training is well established.

## Neuromuscular motility disorders

Motility disorders present with features of gastrointestinal obstruction in the absence of a mechanical cause. The spectrum of motility disorders ranges from relatively benign conditions such as

gastro-oesophageal reflux and functional constipation, to life-threatening illnesses such as chronic intestinal pseudo-obstruction. It can result from any process that interferes with coordinated patterns of propulsive movement of intestinal musculature. Chronic disorders of motility account for 15% of patients with intestinal failure necessitating the use of parenteral nutrition (Connor et al., 2006) and irreversible cases may require intestinal transplant (Gupte et al., 2007).

Intestinal pseudo-obstruction can be divided into acute or chronic. Chronic pseudo obstruction can be primary or secondary to systemic illness. Primary pseudo-obstruction is a result of disorders of intestinal smooth muscle (myopathic) or myenteric plexus (neuropathic), and can involve either the whole of or a localized segment of the bowel (Box 26.4). Neuropathic disorders are more common and may be primary or secondary (e.g. *in utero* insults such as fetal alcohol syndrome or postnatal injuries such as ischaemic events or viral infections; Rudolph et al., 1997). Antroduodenal manometry measures the intraluminal pressure of the antrum and duodenum and is useful to distinguish myopathy (contraction amplitude is reduced but spatial and temporal organisation is preserved), from neuropathy (contractions have normal amplitude but are uncoordinated and lack normal physiologic patterns) (Hyman et al., 1993).

Mitochondrial disorders such as mitochondrial neurogastrointestinal encephalopathy (MNGIE; an autosomal recessive multisystem disorder caused by thymidine phosphorylase deficiency) may also be complicated by pseudo-obstruction, with gastrointestinal symptoms (diarrhoea, dysphagia, and failure to thrive) often preceding the neurological dysfunction (leucoencephalopathy, external ophthalmoparesis and demyelinating peripheral neuropathy) (Shoffner et al., 2010). Recently, abnormalities of the gastrointestinal pacemaker cells, the interstitial cells of Cajal, have been described in patients with motility disorders. In most paediatric

cases, symptoms are present from birth or early infancy. Pain is usually a prominent feature and is a result of uncoordinated contraction of bowel musculature (Takahashi, 2005).

## Management

Management requires a multidisciplinary team that includes a gastroenterologist, surgeon, dietician, and psychologist. Chronic abdominal pain or the fear of pain is a common problem in children with chronic intestinal pseudo-obstruction. Luminal dilatation, repeated invasive procedures, and mucosal inflammation may all contribute to the development of visceral hyperalgesia with sensitization of peripheral and central pain pathways (Anand et al., 2004; Christianson et al., 2009; Feng et al., 2012). The stress of chronic disease can also influence pain report and altered family dynamics (see also Birnie et al., Chapter 12; Fogeron and King, Chapter 13, this volume).

Analgesics may have limited efficacy, and use of morphine can worsen symptoms due to further slowing of gut (Brunton et al., 2011). Controlling bowel dilatation and inflammation can reduce pain. Prokinetics used to improve gastric emptying and gut motility include erythromycin (Ng et al., 2012), domperidone, and neostigmine in severe cases (Gmora et al., 2002). Octreotide is being increasingly studied as a prokinetic to increase small intestinal motility, inhibit gastric emptying, and gallbladder contractility, but benefit has only been reported in adults (Soudah et al., 1991).

Stimulant laxatives have shown to be beneficial in relieving constipation as well as increasing motility (Connor et al., 2006). Reduced motility is also associated with bacterial overgrowth which causes further mucosal inflammation and damage, and worsens the gastrointestinal motility. Oral antibiotics help reduce inflammation and reduce distension by limiting gas-forming bacteria. Probiotics along with antibiotics have also been used in cases of overgrowth though their superiority above a placebo is yet to be proven (Shanahan, 2003). A dilated non-motile segment of the gut can be surgically removed or gastrostomy, jejunostomy, or loop enterostomy may be required to shorten the gut and facilitate transit of intraluminal contents, and can improve enteral feed tolerance in some cases (Shibata et al., 2003). Small intestinal transplantation is indicated in total parenteral nutrition (TPN)-dependent pseudo-obstruction patients with life-threatening complications of PN or with dwindling venous access (Mittal et al., 2003).

## Conclusion

Pain is an important and common symptom of gastrointestinal disease. Pain may be the presenting feature, or an indicator of acute complications, that requires symptomatic treatment until the underlying gastrointestinal disorder is controlled by specific treatments. Pain needs to be interpreted in the context of any known pathology, potential new pathology, and the impact of pain on functioning, and persistent or chronic pain associated with gastrointestinal disease requires coordinated interdisciplinary management.

## CHAPTER 27

# Postoperative pain management

Richard F. Howard

### Introduction

Postoperative pain management begins prior to surgery and includes not only the prevention and pharmacological treatment of pain, but also a holistic and well-coordinated strategy that allays fears and anxieties, and allows children and their carers to participate in the selection and implementation of safe and suitable analgesia. Admission to hospital for surgery is a significant and potentially traumatic event. Coping with a strange and unknown environment, fear of separation, anticipation of painful procedures, and postoperative pain or adverse effects such as nausea are all prominent causes of anxiety and stress that can increase the perception of pain and impact on the quality of perioperative care. Therefore, a successful postoperative pain management programme will include: ongoing training of hospital staff, adequate preparation of children and families that provides timely verbal and written information, and the development and implementation of audited institutional analgesic protocols that ensure the safety and efficacy of pain management strategies in a child-friendly and secure environment.

### Aims

- ◆ Understand basic principles of postoperative analgesia.
- ◆ Ability to select an age-appropriate postoperative pain assessment tool.
- ◆ Understand the pharmacology, advantages and disadvantages of the principal analgesics, and analgesic techniques.
- ◆ Ability to describe suitable analgesic regimens for frequently encountered surgical procedures and in special situations.

### General principles

Postoperative pain is predictable, but pain intensity and the response to analgesia are subject to many different patient-determined variables that are not fully predictable. Therefore, postoperative pain should be anticipated and its intensity assessed frequently during the postoperative period so that appropriate analgesia can be administered promptly, and the response to treatment assessed. Analgesia should be planned according to the expected intensity and duration of pain, but must always be titrated against clinical

response, as treatment must be flexible enough to adapt to inter-individual variation and unexpected circumstances or events. Side effects, such as PONV (postoperative nausea and vomiting), oversedation, or depression of respiration should also be anticipated, monitored, and managed.

Pain after surgery can vary in intensity and duration, but is virtually always greatest in the early perioperative period. Pain intensity decreases in the succeeding days or weeks depending not only on the type and extent of surgery but also on less predictable inter-individual factors, but can normally be expected to resolve spontaneously over time. In practical terms this implies that in the first postoperative hours and days analgesia should be given regularly, by the clock, until requirements start to fall. Analgesia can then be given 'when required' at times when pain is reported or measured, or pain is anticipated, e.g. prior to mobilization. A number of professional organizations have produced detailed and helpful guidelines on the analgesic management of postoperative pain in children. 'Good Practice in Postoperative and Procedural Pain' from the Association of Paediatric Anaesthetists of Great Britain and Ireland are comprehensive, systematically developed, evidence-based guidelines on procedure-specific analgesic strategies for postoperative pain in neonates and children (Howard et al., 2012). 'Acute Pain Management: Scientific Evidence' from the Australian and New Zealand College of Anaesthetists (Macintyre et al., 2010), and 'Practice Guidelines for Acute Pain Management in the Perioperative Setting' from the American Society of Anesthesiologists also include advice on the management of postoperative pain in children (American Society of Anesthesiologists, 2012). The paediatric anaesthesiologist is responsible for the selection and initiation of an appropriate perioperative analgesic regimen. In many institutions ongoing care is devolved to a multidisciplinary postoperative pain management service, but all providers of postoperative pain treatment should be familiar with the methods, indications, doses, and side effects of the most commonly used analgesics and analgesic techniques.

### Negative effects of postoperative pain

Aside from its unpleasant and distressing qualities, poorly managed pain has negative physiological, psychological, and behavioural consequences. Changes in cardiorespiratory, gastrointestinal, endocrine, and immune function that can be prevented by effective

analgesia are known to occur (see *Acute Pain Management: Scientific Evidence* (3rd edition) for an up-to-date account; Macintyre et al., 2010). Postoperative pain can delay re-mobilization and recovery from surgery and can lead to undesirable long-term effects.

Pain and injury during infancy and childhood can adversely influence pain processing mechanisms in later life, including the response to subsequent pain and injury many years later (see Walker, Chapter 3, this volume). In addition, a small proportion of children may experience persistent postsurgical pain for months or years. Predisposing factors include poorly controlled postoperative pain, extensive or repeated surgery involving nerve damage, and psychological vulnerability (Kehlet et al., 2006; Macintyre et al., 2010; Macrae, 2008). Poorly managed postoperative pain also contributes to adverse and problematic changes in children's behaviour and sleep pattern, which may be observed for prolonged periods after surgery, and cause considerable distress and disruption to family life (Karling et al., 2007; Kotiniemi et al., 1997a; Power et al., 2012).

### Postoperative pain management services

Anaesthesiology-led acute pain management services were developed to improve the quality and consistency of care following surgery. Their responsibilities include: provision of education programmes for staff, provision and maintenance of specialized equipment (such as patient-controlled analgesia (PCA) pumps), and overall supervision of pain management and recognition/management of side effects or complications (Box 27.1).

Multidisciplinary institutional Pain Management Services have been established in many hospitals to fulfil this role, several models have been described; they are an essential resource to ensure the quality and consistency of care (Lloyd-Thomas and Howard, 1994; Shapiro et al., 1991; Stomberg et al., 2003). Such services have facilitated the introduction of complex and innovative infusion techniques for pain management in children including PCA, nurse-controlled analgesia (NCA), and continuous regional local anaesthesia (LA), e.g. epidural and paravertebral blocks.

### Pain assessment and measurement

Effective pain assessment is central to the prevention and relief of postoperative pain (Finley et al., 2005; Howard, 2003; Taylor et al., 2008; Walter-Nicolet et al., 2010). Postoperative pain should be assessed frequently, its intensity documented, and appropriate remedial action taken when indicated. The outcome and effectiveness of pain management strategies should then be confirmed by

re-assessment; thereby establishing a cycle of evaluation and treatment that should continue throughout the postoperative period (Howard, 1997). This requires training of health care professionals in the principles of acute pain assessment and the selection and use of structured pain measurement tools that are suitable for the developmental age of the child and the context in which they are to be used. As postoperative pain management must often continue at home following discharge from hospital, parents and carers may also require guidance and instruction on the assessment of pain.

### Basic principles of measurement

For pain to be measured as accurately as possible, the principles underpinning assessment at different developmental ages and in different settings must be understood. Standardized pain measurement tools use various different methods of self-report or observations to quantify pain intensity. Older children are able to use self-report scales such as the visual analogue scale (VAS) or numerical rating scale (NRS) but these methods are not accurate in children who are too young to understand such concepts and cannot be used in infants and pre-verbal or non-verbal children. In order to overcome these obstacles a variety of scales have been devised using three basic methods of measurement:

1. Self-report (e.g. using diagrams or pictures).
2. Observations of behaviour.
3. Observations of physiological parameters.

As some of these methods are relatively indirect, and not appropriate for all ages and all settings, a pain measurement tool should be scientifically 'validated' prior to its adoption for clinical use. An important consequence of this is that pain measurement tools should not generally be adapted or changed from their original validated form, as even minor adaptations can change the psychometric properties of the tool and alter its accuracy (Howard et al., 2012). Validation of pain assessment and measurement tools and detailed description of tools suitable for different ages and settings are covered in more detail elsewhere (see Brummelte et al., Chapter 38; Chorney and McMurty, Chapter 37; Lee and Stevens, Chapter 35; von Baeyer, Chapter 36, this volume).

Children's self-report of pain is the preferred approach whenever possible, and is usually feasible in children older than 5 years (Stinson et al., 2006). An observational measure should be used in conjunction with self-report with 3- to 5-year-olds because the evidence for the reliability and validity of self-report measures of pain intensity alone in this age group is quite limited, and a number of potential problems and biases have been identified when children do not fully understand the scale or the concepts underpinning it (Howard et al., 2012; von Baeyer et al., 2009a). Physiological measures, such as changes in cardiovascular or respiratory parameters are unreliable indicators of pain as they are very non-specific and therefore prone to error. Their use in clinical practice is unproven and therefore they are not recommended as a sole modality, however physiological measures are sometimes used in combination with observations of behaviour in some 'composite' pain assessment tools (Buttner and Fincke, 2000; van Dijk et al., 2001).

### Measurement tools for postoperative pain

A considerable number of acute pain measurement tools exist, but despite the availability of tools they are not always used consistently or

#### Box 27.1 Role of postoperative Pain Management Services

well (Broome et al., 1996; Franck and Bruce, 2009; Karling et al., 2002). An evidence-based guideline 'The Recognition and Assessment of Acute Pain in Children' that provides an evaluation of many currently available tools and advice on selecting appropriate tools has been recently revised by the UK Royal College of Nursing (RCN, 2009).

The suitability of a pain assessment tool depends on the age, cognitive level, language, ethnic/cultural background of the child, the setting for which it is to be used and the tool's psychometric properties i.e. validity, reliability, etc. (Breau and Burkitt, 2009; Mathew and Mathew, 2003; Merkel et al., 2002; Stinson et al., 2006; von Baeyer, 2006; von Baeyer and Spagrud, 2007). All such factors should be taken into consideration when making choices about which acute pain measurement tool to use.

Self-report scales suitable for postoperative pain include the linear VAS, NRS, and diagrammatic scales such as the Faces Pain Scale Revised (FPS-R; Hicks et al., 2001; von Baeyer et al., 2009b) and the Wong-Baker Faces scale (Wong and Baker, 1988). Observational scales include the Face, Legs, Activity, Cry, Consolability (FLACC) scale and the COMFORT scale (Merkel et al., 2002; van Dijk et al., 2005). For children with neurocognitive deficits or developmental delay, a small number of special pain measurement tools have been devised. Examples are the Non-communicating Children's Pain Checklist-Postoperative Version (NCCPC-PV) that is valid for 3- to 19-year-olds, and the Paediatric Pain Profile (PPP) valid for 1 to 18 years (Breau et al., 2002; Hunt et al., 2004). The FLACC scale, one of the most widely used tools in clinical practice, has also been adapted (revised FLACC) and validated for use with cognitively impaired children (Malviya et al., 2006). The Postoperative Pain Measure for Parents has been specially devised and validated for parents to assess their child's pain (Chambers et al., 1996). For postoperative pain assessment in children of normal cognitive ability, Table 27.1 shows some of the most suitable and widely used tools.

## Analgesia

Analgesics and analgesic techniques are selected according to the expected intensity and duration of postoperative pain. Analgesic

**Table 27.1** Measures for postoperative pain by age

Child's age <sup>a</sup>	Measure/tool <sup>b</sup>
Newborn-3 years old	COMFORT or FLACC
4 years old	FPS-R + COMFORT or FLACC
5-7 years old	FPS-R
8 years and older	VAS or NRS or FPS-R

<sup>a</sup>Assuming normal cognitive development.

F. et al, Special Issue: Good Practice in Postoperative and Procedural Pain Management, 2nd Edition, *Pediatric Anesthesia*, Volume 22, Issue Supplement s1, pp. 1-79, Copyright © 2012 Blackwell Publishing Ltd, <http://onlinelibrary.wiley.com/journal/10.1111/%28ISSN%291460-9592>.

requirements fall with time as pain intensity decreases, and the 'reverse pain ladder' concept is often used to provide a simple guide to treatment (Figure 27.1). Local anaesthesia combined with two or more systemic analgesics such as paracetamol, non-steroidal anti-inflammatory drug (NSAID), and an opioid are often used as part of a multimodal analgesic strategy (see later in chapter). Physical and psychological techniques, including reassurance, distraction, and hypnosis, have proven effectiveness for brief procedural pain (see Taddio, Chapter 19, this volume). Non-pharmacological techniques also have a role as a supplement to analgesic drugs in the perioperative period, by helping to allay fear and anxiety during potentially painful care such as blood sampling, placing, changing or removing nasogastric tubes, bladder catheters, chest drains, or sutures and during postoperative mobilization.

## Routes of drug administration

The route of administration of a drug is an important determinant of its effectiveness. However, in the postoperative setting the number of routes may be limited (e.g. during fasting and nil oral periods), and choice of route is an important issue that requires discussion with children and their families (Seth et al., 2000). It is well known that children dislike needles, but children are sometimes

**Figure 27.1** Reverse pain ladder.

reluctant to take oral medications if they find their taste or consistency unpalatable, rectal administration may be unacceptable to some families, and children may, or may not, be willing or able to use a self-administration technique such as PCA. It is important that children’s views are taken into consideration whenever possible and that their wishes and those of their families are respected when decisions are made regarding the route and method of pain relief. When available, the oral route is usually preferred above all others for its safety, simplicity, and convenience, although acceptable formulations or combinations of drugs with favourite drinks or food may be necessary for them to be tolerated. In the immediate perioperative period, and sometimes for many days later depending on the type of surgery, the oral route cannot be used and so drugs are most commonly given by the intravenous (IV) route.

An advantage of LA techniques is that they may reduce the need for analgesia during the early postoperative period when the oral route is not available. ‘Single-shot’ nerve blocks (see ‘Multimodal analgesia’ section), performed under general anaesthesia typically provide analgesia of several hours’ duration, which is often sufficient for resumption of oral intake. Other options when analgesics cannot be given orally include subcutaneous, sublingual, and buccal routes. Subcutaneous opioid infusions are particularly useful when IV access is difficult or limited and must be preserved for other drugs or treatments such as chemotherapy or parenteral nutrition. In the future, novel technologies such as transcutaneous drug administration may become a viable choice in the perioperative period, but at present the available formulations are generally unsuitable.

Multimodal analgesia

Since the approach of multimodal analgesia was first suggested (Kehlet, 1997), the efficacy of combinations of analgesics and analgesic strategies have been shown in numerous studies of postoperative pain in children. However, there have been few studies with sufficient sensitivity to demonstrate the individual contribution of a single analgesic. In theory, the use of multiple analgesics that are effective on different mechanisms of nociception will increase efficacy whilst minimizing the dose, and therefore potential for adverse effects, of each drug. For example, avoiding side effects such as sedation, PONV, or respiratory depression from higher doses of opioid analgesics is clearly an important potential advantage. A recent meta-analysis of studies involving the use of NSAIDs has shown that as part of a multimodal technique they can also reduce opioid consumption and the incidence of PONV (Michelet et al., 2012). Adjuvant analgesics such as ketamine are sometimes

co-administered with opioids to improve postoperative analgesia and reduce opioid dose but supporting evidence is weak and optimum doses are not known (Dahmani et al., 2011; Elshammaa et al., 2011). Similarly, there has been recent interest in the use of pre-operative gabapentin prior to potentially nerve-damaging major surgery; postoperative opioid requirements may be reduced in children but again few data are available (Rusy et al., 2010). LA blocks, such as wound infiltration and simple nerve blocks such as ilio-inguinal or penile dorsal nerve block, are relatively easy to perform and analgesia extends into the early postoperative phase following a single injection, thereby reducing the need for other analgesics. These techniques, or ‘single-shot’ caudal epidural block, can also be combined with non-opioid analgesics after a range of ‘intermediate’ surgeries at and below the inguinal region, e.g. inguinal hernia repair, orchidopexy or circumcision. For guidance on which combinations are effective for individual procedures, see evidence-based guidelines (Howard et al., 2012; Macintyre et al., 2010).

Selection of an appropriate analgesic requires specific knowledge of its developmental pharmacology; a summary for some of the most important analgesics used for postoperative pain is given here, for more detailed information see chapters where indicated.

Paracetamol and NSAIDs

Paracetamol and NSAIDs can be used singly or combined for minor surgery and at home following day surgery (see Anderson, Chapter 43, this volume, for detailed pharmacology of paracetamol and NSAIDs). As part of a multimodal analgesic regimen they are used throughout the postoperative period to supplement other techniques (see Figure 27.1).

Paracetamol (acetaminophen)

Paracetamol has been studied extensively in children, its developmental pharmacokinetic characteristics are relatively well understood, and it can be used safely in the neonatal period provided dosage guidelines are followed (Anderson and Palmer, 2006). Paracetamol is available for oral administration in syrup, tablet, and dispersible forms, can be given per rectum (but there is very wide variation in the bioavailability of rectal paracetamol) and an IV preparation of paracetamol is also available. Dosage regimens depend on the age of the child, the route of administration and the duration of treatment (Tables 27.2 and 27.3). Clearance in neonates is reduced, and the volume of distribution is increased, therefore the dose and dose interval are modified for neonates. The maximum

Table 27.2 Paracetamol dosing guide—oral and rectal administration

Age	Route	Loading dose	Maintenance dose	Interval	Maximum daily dose	Duration at maximum dose
28–32 weeks PCA	Oral	20 mg/kg	10–15 mg/kg	8–12 h	30 mg/kg	48 h
	Rectal	20 mg/kg	15 mg/kg	12 h		
32–52 weeks PCA	Oral	20 mg/kg	10–15 mg/kg	6–8 h	60 mg/kg	48 h
	Rectal	30 mg/kg	20 mg/kg	8 h		
>3 months	Oral	20 mg/kg	15 mg/kg	4 h	90 mg/kg	48 h
	Rectal	40 mg/kg	20 mg/kg	6 h		

PCA = post-conceptual age.

**Table 27.3** Paracetamol dosing guide—intravenous administration

Weight (kg)	Dose	Interval	Maximum daily dose
<5 (term neonate)	7.5 mg/kg	4–6 h	30 mg/kg
5–10	10 mg/kg	4–6 h	40 mg/kg
10–50	15 mg/kg	4–6 h	60 mg/kg
>50	1 g	4–6 h	4 g

daily dose of paracetamol is limited by the potential for hepatotoxicity which can occur following overdose (single or repeated doses exceeding 150 mg/kg in total). Multiple therapeutic doses may also lead to accumulation and toxicity in children who are malnourished or dehydrated.

## NSAIDs

NSAIDs are effective for the treatment of postoperative pain, used alone or in combination as part of a multimodal strategy, as they reduce opioid requirements and the combination of NSAIDs and paracetamol produces better analgesia than either drug alone (Michelet et al., 2012). A number of different NSAIDs and formulations are available and suitable for postoperative use, e.g. ibuprofen tablets and syrup, a sublingual dispersible tablet, diclofenac tablets (dispersible and enteric coated), suppositories, and parenteral formulations (Table 27.4). NSAIDs are widely available and generally considered to be safe; nevertheless it is important to understand how their mode of action can make them a potentially undesirable choice of analgesic in certain situations.

The mechanism of action of NSAIDs is via inhibition of cyclooxygenase (COX) activity, thereby blocking the synthesis of prostaglandins and thromboxane. Because COX is ubiquitous and responsible for many physiological regulatory activities NSAIDs have the potential to cause adverse effects, sometimes at therapeutic plasma levels:

- As NSAIDs reduce platelet aggregation and prolong bleeding time, they are contraindicated in children with coagulation disorders or in those who are receiving anticoagulant therapy and relatively contraindicated when there is a high risk of postoperative bleeding.
- NSAIDs can cause gastric irritation and gastrointestinal bleeding, and therefore are relatively contraindicated in children with a history of peptic ulcer disease. The risk of adverse gastrointestinal effects is low when NSAID use is limited to 1 to 3 days, e.g. in the postoperative period, and may be further reduced by co-prescription of proton pump inhibitors such as omeprazole, or histamine ( $H_2$ ) receptor antagonists in patients at higher risk. NSAIDs can inhibit prostaglandin mediated renal function and this effect is greater in the presence of renal disease and dehydration.
- Renal toxicity is very low in healthy children, but NSAIDs should not be administered concurrently with other agents known to cause nephrotoxicity.
- NSAIDs have the potential to exacerbate asthma in a predisposed subset of NSAID-sensitive asthmatics who show cross-sensitivity with aspirin. It is estimated that 2% of asthmatic children are susceptible to aspirin induced bronchospasm, and 5% of this subgroup are likely to be cross sensitive to other NSAIDs. A history of previous uneventful NSAID exposure should be established in

**Table 27.4** Dosage of NSAIDs

NSAID	Dose	Interval	Maximum daily dose
Ibuprofen	5–10 mg/kg	6–8 h	30 mg/kg
Diclofenac	1 mg/kg	8 h	3 mg/kg
Ketorolac	0.5 mg/kg	6 h	2 mg/kg
Naproxen	7.5 mg/kg	12 h	15 mg/kg
Piroxicam	0.5 mg/kg	24 h	0.5 mg/kg
Ketoprofen	1 mg/kg	6 h	4 mg/kg

asthmatic children whenever possible but there is reassuring data regarding the safety of short-term use of ibuprofen and diclofenac in asthmatic children (Lesko et al., 2002; Short et al., 2000). Nevertheless, they should be avoided in children with severe acute asthma, and are contraindicated in status asthmaticus.

- Studies in animals using high doses of ketorolac found that bone fusion was delayed: This has led to concern that the use of NSAIDs in children may delay bone healing following fracture or bony surgery. This has not been supported by human studies and the analgesic benefits of short-term NSAID use often outweigh the hypothetical risk of delayed bone healing (Howard et al., 2012).

The risks of side effects are often considered to outweigh the analgesic benefits in infants and neonates and so these drugs are rarely prescribed for pain for age less than 3 months. Attempts to reduce the undesirable effects of NSAIDs have led to the development of compounds that specifically inhibit COX-2, the COX enzyme responsible for the generation of pain and inflammation. However, these compounds have been shown to cause cardiovascular side effects in adults and have been little studied, and are little used, for postoperative pain in children (Turner and Ford, 2004).

## Opioids

Opioids remain the most potent and efficacious group of systemic analgesics for postoperative pain. They can be given by many routes and are safe for all ages, provided accepted dosing regimens are used and appropriate monitoring and education of staff are in place. Morphine is the prototype opioid; diamorphine, hydromorphone, oxycodone, and tramadol, are frequent alternatives to morphine in the postoperative period, and Table 27.5 shows the relative potency to morphine. The synthetic family of opioids (fentanyl, sufentanil, alfentanil, and remifentanil) have a role after major surgery and in

**Table 27.5** Relative potency of opioids

Drug	Potency relative to morphine	Single dose (oral)	Continuous infusion (IV)
Tramadol	0.1	1–2 mg/kg	100–400 mcg/kg/h
Codeine <sup>a</sup> /dihydrocodeine	0.1–0.12	0.5–1 mg/kg	N/A
Morphine	1	200–400 mcg/kg	10–40 mcg/kg/h
Hydromorphone	5	40–80 mcg/kg	2–8 mcg/kg/h

<sup>a</sup>Relative potency of codeine depends on metabolizer status—see chapter text.

intensive care practice, and can be used intraoperatively to provide analgesia reduce the stress response to surgery. The so-called moderate potency opioids, codeine and dihydrocodeine, are sometimes used for short-term treatment of postoperative pain of low intensity or in non-hospital settings. Codeine is usually not recommended for postoperative pain because it is a pro-drug, and the production of the active metabolite morphine is very variable and unpredictable, and can result in either ineffective analgesia in poor metabolizers (Williams et al., 2001) or relative overdose and toxicity in ultrarapid metabolizers (Kelly et al., 2012; see also Chau and Koren, Chapter 42, this volume). The synthetic opioid pethidine (meperidine) is not recommended for children, due to the adverse effects of its main metabolite norpethidine.

Opioids can cause a wide range of adverse effects but substantial clinical experience in their use in children means that they can be given safely for postoperative pain, provided dosage guidelines and some relatively straightforward management principles are followed. Side effects of opioids such as nausea and vomiting, sedation, and depression of respiration are usually dose related. However, their occurrence is not uniform between different opioids or even between patients taking the same drug. The incidence and severity of side effects in an individual patient are influenced by both the specific opioid, dose, route of administration, genetic, and developmental factors (see also Hathway, Chapter 44; Strassels, Chapter 45, this volume). Appropriate monitoring and adverse effect management should always be included when potent opioids are prescribed, i.e. frequent monitoring of respiratory rate and level of sedation, and prophylaxis and treatment of PONV.

**Intravenous opioid analgesia, PCA, and NCA**

For moderate to severe postoperative pain, especially after major surgery, continuous IV analgesia using opioids is usually indicated, with the addition of intermittent ‘extra’ analgesia when required for breakthrough or incident pain (Howard et al., 2012). In recent years, the techniques of PCA and NCA have also become popular, which allow for bolus administration with a lock-out period, with or without a background infusion. Some institutions have even introduced the concept of PCA-by-proxy (Angelescu et al., 2005; Howard, 2003; Howard et al., 2010; Lloyd-Thomas and Howard, 1994; Nelson et al., 2010). Opioid infusions, including PCA and

NCA, have utilized a range of opioids (e.g. morphine, fentanyl, oxycodone, tramadol) and can provide adequate titration of analgesia with an acceptable level of side effects (Morton and Errera, 2010). Some typical doses and infusion rates for PCA and NCA are given in Tables 27.6 and 27.7.

PCA has been extensively used in children as young as 5 years of age who can understand the necessary concepts, and compares favourably with continuous morphine infusion but with the added benefits of autonomy and ease of titration for patients. PCA infusion programming variables are bolus size (mg/kg), continuous infusion rate (mg/kg/h), and bolus lock-out interval (min). An important difference between PCA in young children and PCA in adults, is that it is not unusual to run a small background infusion for young patients. This is regarded as improving analgesia without compromising safety, provided there is adequate monitoring for sedation and depression of respiration (Morton and Errera, 2010).

NCA is an analgesic infusion where a nurse activates the button to provide on-demand analgesia within pre-established guidelines. NCA can provide safe and flexible analgesia for children who are too young or unable to use PCA; it has been used safely in large numbers of children (Howard et al., 2010; Lloyd-Thomas and Howard, 1994). NCA can also been used in the neonatal period but some dosing modifications have been recommended (see later section related to neonatal analgesia).

**Regional analgesia**  
**Local anaesthetics and techniques**

LA is popular in the perioperative setting because it allows profound and specific analgesia at the site of surgery, often without systemic side effects. The amide LAs bupivacaine, levobupivacaine, and ropivacaine are most often used for perioperative pain, either as a single dose with a duration of action of 2 to 4 h, or by continuous infusion. The principal drawback of LA techniques is the relatively limited duration of action with single-shot intraoperative blocks, and the potential for serious side effects if recommended doses are exceeded (Table 27.8). Strategies designed to prolong the action of LA include the use of infusion catheters near peripheral nerves, into the epidural space, or elsewhere. Vasoconstrictors may be added to reduce the systemic absorption of local anaesthetic

**Table 27.6** Patient-controlled analgesia doses and infusion rates

Opioid	Loading dose (mcg/kg)	Bolus (mcg/kg)	Lock-out (min)	Background (mcg/kg/h)
Morphine	50–100	10–20 (max 1mg)	5–10	0–4
Fentanyl	0.5–1.0	0.25–0.5 (max 50 mcg.)	5–10	0–0.1
Oxycodone	50–100	10–20 (max 1mg)	5–10	0–4

**Table 27.7** Nurse-controlled analgesia doses and infusion rates (not neonates)

Opioid	Loading dose (mcg/kg)	Bolus (mcg/kg)	Lock-out (min)	Background (mcg/kg/h)
Morphine	50–100	10–20 (max 1 mg)	20–30	4–10
Fentanyl	0.5–1.0	0.25–0.5 (max 50 mcg.)	0–30	0–0.1
Oxycodone	50–100	10–20 (max 1 mg)	20–30	0–4

**Table 27.8** Suggested maximum dose of bupivacaine, levobupivacaine, and ropivacaine

Single bolus injection	Maximum dosage
Neonates	2 mg/kg
Children	2.5 mg/kg
Continuous postoperative infusion	Maximum infusion rate
Neonates	0.2 mg/kg/h
Children	0.4 mg/kg/h

and to prolong their effects, and neuraxial analgesics may be been co-administered with the LA to prolong the effect of central nerve blocks (Walker and Yaksh, 2012).

LA techniques include:

- Wound infiltration (often performed intraoperatively by the surgeon).
- Peripheral nerve blocks, e.g. penile dorsal nerve block, ilio-inguinal-iliohypogastric nerve block.
- Field block such as the transversus abdominis plane (TAP) block.
- Plexus blocks, e.g. axillary brachial plexus block.
- Central neuraxial blocks such as caudal epidural block, lumbar or thoracic epidural block, and intrathecal spinal block.

Ultrasound guidance for regional blocks has become popular as it potentially allows greater accuracy in placement of LA and therefore improved safety and effectiveness (Ivani and Mossetti, 2010; Tsui and Suresh, 2010).

Continuous lumbar and thoracic epidural blocks are complex techniques whose potential complications include epidural infection or haematoma that could lead to significant permanent neurological deficit. The safety of these techniques is likely to depend on many factors including training standards and technical proficiency, the use of screening tests for coagulopathy and effective aseptic technique, and the monitoring and management of neurological signs and symptoms. Recent audits of large numbers of continuous epidural blocks have found that the overall risk of permanent neurological harm in children is less than 1:10 000 (Ecoffey et al., 2010; Llewellyn and Moriarty, 2007; Walker and Yaksh, 2012), a figure that is broadly similar to the risk of serious complications following continuous opioid infusions (Howard et al., 2010; Morton and Errera, 2010).

### Neuraxial and adjuvant analgesics

Drugs that produce a specific spinally mediated analgesic effect following epidural or intrathecal administration are referred to as neuraxial analgesic drugs. Clonidine, ketamine, and opioids have been used for neuraxial analgesia (see Table 27.9 for typical doses and side effects). In combination with LA neuraxial analgesics can increase the duration of analgesia but the use of some neuraxial analgesics has declined in recent years; due to side effects in the case of opioids, and because of potential neurotoxicity for ketamine (Engelman and Marsala, 2012; Schnabel et al., 2011; Walker and Yaksh, 2012; Walker et al., 2010).

**Table 27.9** Dose and side effects of epidural neuraxial analgesics

Drug	Single dose	Infusion	Side effects
Clonidine	1–2 mcg/kg	0.08–0.2 mcg/kg/h	Sedation; dose related hypotension and bradycardia (5 mcg/kg); delayed respiratory depression and bradycardia in neonates
Morphine	15–50 mcg/kg	0.2–0.4 mcg/kg/h	Nausea and vomiting; urinary retention; pruritis; delayed respiratory depression
Fentanyl	0.5–1 mcg/kg	0.3–0.8 mcg/kg/h	Nausea and vomiting
Tramadol	0.5–2 mg/kg		Nausea and vomiting

Clonidine is an  $\alpha_2$ -adrenergic agonist and has sedative, anxiolytic, and analgesic properties that can be given orally, transdermally, intravenously, or epidurally. It has an established role as a neuraxial analgesic in paediatric practice as clonidine via the intrathecal or caudal/epidural route has a greater effect than the same dose intravenously (Akin et al., 2010; Disma et al., 2011). Sensitivity to side effects of clonidine (apnoea, oxygen desaturation, and bradycardia) is greater in neonates, and cardiovascular and sedative side effects have been reported following doses of 5 mcg/kg caudal clonidine in children (Schnabel et al., 2011). Epidural clonidine 0.08 to 0.12 mcg/kg/h produces dose-dependent analgesia when added to LA infusion (De Negri et al., 2001), and higher doses of clonidine alone (0.2 mcg/kg/h preceded by bolus of 2 mcg/kg) provide analgesia at rest following abdominal surgery (Klamt et al., 2003).

## Special situations

### Day surgery

Most surgery in children is done on a day-stay basis. Day surgery has social advantages for children and their families, and for health care providers there are significant economic benefits. A long-recognized disadvantage is that potentially large numbers of children suffer unnecessary pain and other symptoms at home after day surgery that can last for several weeks (Kotiniemi et al., 1997b; Power et al., 2012; Wolf, 1999). Ensuring that effective pain management continues at home after day surgery is an important priority. Initiatives designed to improve the quality of care after day surgery include better information for parents about the use of analgesics and non-pharmacological pain management strategies, training in pain assessment, 'take home packs' of medication and rapid access telephone or online support systems. The quality of analgesia at home and the incidence and management of symptoms should always be closely monitored and audited.

### Neonates

Neonates are a particularly vulnerable group who are also susceptible to higher rates of serious complications due to surgery and medications, including analgesics. For example, severe complications following paediatric regional analgesic techniques are rare, but the incidence is higher in neonates and infants: 0.4% versus 0.1% for all regional blocks or 1.1% versus 0.49% for epidural

blocks (Walker and Yaksh, 2012). Similarly, the incidence of serious adverse events during NCA morphine analgesia, at 2.5%, was almost ten times higher in neonates (<1 month of age) compared with 0.27% in those older than 1 month (Howard et al., 2010). In addition, there may be long-term consequences to the developing nervous system as injury, pain, and analgesia have been associated with long-term changes in sensory processing systems in laboratory surgery models and in children following neonatal surgery (Fitzgerald and Walker, 2009; Peters et al., 2005; Schmelzle-Lubiecki et al., 2007; Walker et al., 2009). Drugs such as general anaesthetics and some analgesics with N-methyl-D-aspartate antagonist and/or  $\gamma$ -aminobutyric acid agonist activity are known to increase neuronal apoptosis (spontaneous neuronal cell death) in the developing brain in rodents and primates (Stratmann, 2011). Clearly, immaturity of organ systems renders them vulnerable to dysregulation and even permanent damage necessitating modification of analgesic drug choice and dosage regimens together with increased vigilance for adverse effects by staff with specialist training and skills.

Analgesic doses must be modified in the neonatal period as rapid and profound changes in body composition and organ function occur in the first few weeks of life. Changes in body water, fat distribution and composition, and plasma protein binding capacity alter the volume of drug distribution and other pharmacokinetic variables in neonates. Immaturity of hepatic metabolizing systems and slower renal elimination prolong the elimination time of many drugs such that doses and dose intervals must be modified. Larger inter-individual variations in the response to analgesics and their adverse effects add further unpredictability (Walker and Howard, 2004; see also Chau and Koren, Chapter 42, this volume).

### Paracetamol

The pharmacokinetics of paracetamol in neonates has been relatively well studied (Allegaert et al., 2011; see also Anderson et al., 2002, Chapter 43, this volume), with recommendations for doses adjusted for age (see Tables 27.3 and 27.4). Although paracetamol is used extensively in the neonatal period the potential for overdose due to drug accumulation with repeated dosing, prescription or administration error are always present.

### NSAIDs

Although this group of drugs is used for pharmacological closure of patent ductus arteriosus in premature neonates they are not generally a suitable choice for postoperative pain until after 3 months of age. Prostaglandins, inhibited by NSAIDs, have multiple regulatory roles and are especially important in early development. Increased risk of pulmonary hypertension, changes in cerebral blood flow, decreased renal function- ibuprofen has been shown to reduce glomerular filtration rate in neonates by 20%, deficient thermoregulation, and disrupted sleep cycle are just some of the increased risks anticipated with the use of these drugs in the neonatal period.

### Opioids

Plasma clearance of opioids is reduced in neonates, and correlates with weight and post-conceptual age (Bouwmeester et al., 2004; Kart et al., 1997; Lynn et al., 2000). Although the plasma concentration of morphine associated with analgesia is not known, both pharmacokinetic and pharmacodynamic factors contribute to reduced dose requirements in neonates (see also Hathway, Chapter 44; and

Strassels, Chapter 45, this volume). Opioids are indicated postoperatively and are safe in neonates, provided dosage guidelines are followed with individual titration against response. The risk of respiratory depression is higher in neonates receiving postoperative NCA, particularly those with intercurrent illness or prematurity (Howard et al., 2010; Morton and Errera, 2010). Adequate training of staff and monitoring for side effects is essential, and in some centres may warrant nursing in high-dependency or intensive care settings. NCA regimens for neonates frequently utilize bolus-only administration without background infusions (Howard, 2010; Howard et al., 2010).

### Local anaesthesia

LA techniques are an appealing option for the immediate perioperative period as the need for general anaesthesia and potent systemic analgesics is reduced. Nevertheless, the toxicity of LAs is also greater in neonates and so maximum recommended doses are lower, and must not be exceeded (Berde, 1993). Bupivacaine is highly protein-bound to  $\alpha$ 1-acid glycoprotein and albumin. The concentration and affinity of  $\alpha$ 1-acid glycoprotein for bupivacaine is reduced in neonates, thus increasing the proportion of free unbound drug, but during epidural infusion techniques reduced hepatic clearance of amide LA is the more important factor causing accumulation of bupivacaine than reduced protein binding capacity, particularly as protein levels tend to increase in response to surgery (Howard et al., 2012; see Table 27.9 for suggested maximum doses).

#### Case example: tonsillectomy pain

Adam, age 5, weight 20 kg has recurrent tonsillitis and is scheduled for adeno-tonsillectomy. The hospital he attends has an anaesthesia pre-assessment clinic, runs a programme of pre-admission visits to the hospital for children and their parents, and has an acute pain management service.

*At pre-assessment 2 weeks before surgery* Adam's health is found to be good except for mild asthma for which he takes salbutamol and beclomethasone by inhaler. The pre-assessment nurse asks if Adam has ever taken NSAIDs such as ibuprofen in the past, and his mother says that she has never given them to him because he has asthma. The nurse notes this, and mentions that it is sometimes OK to give NSAIDs to children with asthma. Adam's family are given a leaflet explaining the adeno-tonsillectomy surgery that includes discussion of postoperative pain and how it will be managed. As pain after tonsillectomy can persist for several days following discharge the need for analgesia at home, possibly for as long as 10 days, is noted. The leaflet includes a brief explanation of pain assessment procedures and an example of a self-report pain scale, using diagrams of faces.

*One week prior to surgery* Adam and his mother also attend the pre-admission visit where a further explanation of pain assessment takes place. A nurse instructs Adam in use of the faces pain self-report scale, and Adam's mother asks questions about what she will need to do for pain at home.

*On the day of surgery* the anaesthesiologist discusses the perioperative pain management plan with Adam and his mother during the pre-anaesthesia consultation. He explains that during the surgery the tonsillar fossa will be infiltrated with LA, which will be effective in the early postoperative period, but the effects

will wear off after 1 or 2 h. Adam will also receive paracetamol (acetaminophen) and an opioid (fentanyl), during the surgery plus prophylactic medication for PONV. Analgesia will be given every few hours, and more will be available if needed.

Adam's mother is concerned about the potential use of NSAIDs, and the anaesthesiologist explains the risks and benefits of NSAIDs after tonsillectomy. Although risks are low, they decide not to use NSAIDs without further discussion. Adam wakes up in the post-anaesthesia care unit (PACU), feels disorientated, finds it difficult to swallow, and he is in pain. The PACU nurse administers IV morphine analgesia and Adam sleeps for a time, and then wakes up and is transferred to the ward area for the next few hours. After a while Adam's throat hurts a lot and it is difficult to swallow, and he indicates the penultimate face on the faces pain scale. He is given further paracetamol and some oral morphine, but also feels nauseous. As he continues to have pain, the nurse calls the anaesthesiologist who assesses Adam and discusses analgesic options with Adam's mother. The anaesthesiologist recommends giving a dose of ibuprofen (an NSAID) and Adam's mother agrees. About 45 min later, Adam seems much better and he is prescribed regular alternating doses of paracetamol and ibuprofen, and additional oral morphine if needed.

The next morning Adam is due to be discharged, but his mother is quite concerned about managing Adam's pain at home. A nurse explains that for 3 days she should continue to give regular medication (paracetamol and ibuprofen 'by the clock') unless any side effects occur, and thereafter to give analgesia at bedtime and according to pain assessments. Adam's mother is given written instructions and a telephone number to call if she needs further advice, and she is told that someone from the hospital will contact her the following day. After returning home Adam's mother speaks to a nurse as planned, she is asked about Adam's pain and is given advice, reassurance, and a reminder of who to contact if necessary. Adam recovers well and returns to school after a further week.

## CHAPTER 28

# Pain in palliative care

Ross Drake and Renée McCulloch

### Summary

Pain in palliative care for children is common and is often a result of different combinations of nociceptive (somatic and/or visceral) and neuropathic pain rather than being from a single aetiology. This pain is best addressed through a collaborative, interdisciplinary team employing a holistic approach to the child and their family. Medication, particularly opioids, has a central role in management but attempting to relieve pain without addressing the child's non-physical concerns is likely to lead to frustration. The expectation should be for exemplary control of pain bearing in mind some of the syndromes faced can be complex and may require quite sophisticated techniques to be managed appropriately including the use of surgical and anaesthetic procedures.

### Introduction

Palliative care for children is the active total care of the child's body, mind, and spirit, and also involves giving support to the family. Health providers must evaluate and alleviate a child's physical, psychological, and social distress (World Health Organization (WHO), 1998) through the prevention and relief of suffering by early identification and impeccable assessment and treatment of pain (WHO, 1996).

Two aspects of this statement resonate loudly with health care professionals involved in palliative care: the reference to the multi-dimensional nature of assessment and management necessitating a collaborative, interdisciplinary team approach by paediatric trained professionals and the elevation of pain to a symptom requiring meticulous attention.

Pain is, arguably, the most feared symptom faced by children and their families during their palliative journey. Pain has a consistently high prevalence (Drake et al., 2003; Sirkia et al., 1998; Wolfe et al., 2000) but the ability to satisfactorily control pain can be quite variable (Sirkia et al., 1998; Wolfe et al., 2000) and changes over the final week of life (Drake et al., 2003).

A significant key to success involves effective communication just as much as choosing the right intervention. Open, honest discussion of assessment and treatment strategies provides the foundation of a trusting therapeutic relationship that, in turn, allows for dialogue about anxieties and misconceptions that can, if not addressed, hamper appropriate management.

Unfortunately, the evidence available to support therapeutic approaches to deal with children's pain during palliative care is sparse. This requires clinicians to use evidence from studies on acute pain in children and the literature of adult palliative care. This latter source demands cautious extrapolation to children, especially those

with non-malignant conditions. Conditions experienced by children are quite different from adults as are the anatomy and physiology of the child and their cognitive responses to pain and pain therapies. However, even in the absence of evidence, safe and effective management can be achieved through a sensible, empirical approach centred on good observation and evaluation and an understanding of the disease process and therapeutics being used.

### World Health Organization guidelines

The WHO has influenced the management of pain in children's palliative care through the publication in 1998 of a simple guideline outlining the rational stepwise approach to the management of cancer pain in children (WHO, 1998). The guidelines were effective in providing analgesia in this group (Zernikow et al., 2006). Clinically, their use was broadened to include children with non-malignant conditions although this expansion was never validated; an important factor as over half of children have a non-malignant condition (Drake et al., 2003; Feudtner et al., 2011).

In 2012 the WHO published a major review of the guidelines (WHO, 2012) with the new iteration based on the best available evidence and extended to cover persistent pain in children with medical illnesses. The analgesic ladder remains at the heart of the guidelines but the three-step ladder was reduced to two steps by removing the measure for mild to moderate pain. In effect, minor opioids are replaced with a low dose of a major opioid. The choice of analgesia is determined through 'impeccable assessment' and the point of entry established by the severity of pain.

The ladder is supported by three other 'rules' which remain unchanged to complete a logical framework for prescribing.

- ♦ By the clock—encourages the regular scheduling of analgesia to ensure a steady blood concentration and to reduce the peaks and troughs of intermittent dosing. This regular dosing should be supplemented with 'as needed' breakthrough doses for pain that may emerge.
- ♦ By the appropriate route—requires the least invasive route of administration to be used; the oral route is preferable in most circumstances.
- ♦ By the child—promotes individualized treatment according to the assessed need.

The reliance on opioids for pain management in palliative care is a distinguishing factor. However, there are occasions when children who could benefit from opioid therapy are, or their family are, unwilling to have the child take opioids. This is usually based

on misconceptions about their use and the perception that opioids mark 'the beginning of the end'. These fears need to be explored and correct information provided. Unfortunately, reservations can be so powerful that a prescription for an alternative agent may be required even if it has, potentially, inferior efficacy. Simply, there is little point in prescribing the ideal drug if it is clear that the child and/or family will not comply with its administration. This makes the availability of effective alternatives (perceived to be safer) of real practical value.

Opioids are introduced once simple analgesia is no longer effective or if assessment indicates the child is having more than mild pain. The prescribing of opioids has been covered in depth by Strassels (Chapter 45, this volume), but in palliative care follows the 'by the clock' rule reaffirmed in the 2012 WHO guidelines with both continuous and 'as needed' or rescue analgesia being made available as highlighted in the following clinical case example.

### Case example

A 10-year-old boy presents with relapsed, metastatic hepatoblastoma for which there are no further curative options. He has intermittent albeit frequent aching epigastric pain averaging 7/10 intensity. This equates to severe pain and an opioid in the form of oral morphine is commenced.

#### Initiation

An initial oral dose of 6 mg (0.2 mg/kg/dose) immediate-release morphine preparation is prescribed as a regular 4 h dose. An additional 6 mg rescue dose is advised to be taken as needed up to every hour (one-sixth of the total daily dose of 36 mg, i.e.  $6 \text{ mg} \times 6 = 36 \text{ mg}$ ).

#### Titration

Day 1: the child requires 5 rescue doses (30 mg) in 24 h.

Day 2: the child requires 3 rescue doses (18 mg) in 24 h.

At the 48 h review he has averaged 4 rescue doses each day indicating the regular dose needs to be increased by 24 mg (i.e.  $4 \times 6 \text{ mg} = 24 \text{ mg}$ ).

*Regular dose:* new total daily dose is  $36 \text{ mg} + 24 \text{ mg} = 60 \text{ mg}$  over 24 h or 10 mg every 4 h.

*Breakthrough dose:* remains one-sixth of total daily dose or 10 mg ( $60 \text{ mg} \div 6$ ) as needed up to every hour.

Day 3: the child requires 1 rescue dose (10mg) in 24 h.

Day 4: the child requires no rescue doses in 24 h.

At 48 h review the child has averaged less than 1 rescue dose each day indicating the regular dose does not need to be increased. The regular morphine dose can be converted to a long-acting preparation.

*Regular dose:* total daily dose is 60 mg or 30 mg twice daily of a slow-release morphine formulation.

*Breakthrough dose:* remains 10 mg of immediate-release morphine.

This example illustrates that the *titration* phase has ended and the *maintenance* phase begins. The maintenance phase starts when a reasonably stable dose of regular opioid has been reached and the total daily dose no longer needs adjustment. In reality this phase represents a period of slower titration where further increases may be required for disease-progression and, on occasion, opioid tolerance.

Continual assessment and review is required to ensure adequate analgesia is ongoing.

## Challenging pain syndromes in palliative care

### Episodic pain—breakthrough pain versus incident pain

Episodic pain in palliative care is usually seen in children with advanced cancer and equates to either 'breakthrough' or 'incident' pain. These are two distinct entities although the terms are often used, incorrectly, interchangeably.

Breakthrough pain has been defined as 'a transitory exacerbation of pain superimposed on a background of persistent usually well controlled pain' (Gomez-Batiste et al., 2002). The prevalence in children requiring palliative care is unknown although one study (Friedrichsdorf et al., 2006) indicated over 50% of children with cancer ( $n = 27$ ) will experience one or more episodes. The solution is to adjust the dose of medication, usually an opioid, as described in the clinical case example. When the pain occurs at the end of a regular dose this is known as 'end-of-dose failure'. The remedy for this situation may simply be to increase the dose but failure (pain breakthrough) further away from the next dose may require shortening of the interval between doses. For example, consistent breakthrough pain at hour 9 of a 12 h sustained-release preparation may require 8-hourly dosing of the medication.

Incident pain refers to an intermittent or episodic, often severe, pain associated with specific events or activity such as weight bearing or coughing and escalation may be related to complications such as a pathological fracture. Management necessitates identifying, anticipating, and, if possible, avoiding the provoking factors. The requirement of any pharmacological intervention is for the medication to be immediately available, have a very rapid on- and off-set of action (Chu et al., 2008) and be highly potent. This can complicate management as analgesics are often too slow to be effective during the pain episode and cause toxicity as the agent becomes fully active when the pain naturally subsides.

The administration of parenteral short-acting opioids and nasal or buccal formulations come closest to the ideal. Interventional approaches should be contemplated especially when incident pain is unresponsive to medication. These range from simple measures such as a sling to immobilize the affected part to radiation therapy or chemotherapy to more sophisticated surgical or anaesthetic techniques.

### Episodic pain—muscle spasm

Episodic pain may also reflect pain of a sporadic nature as seen with intestinal colic or muscle spasm. Muscle spasm is a potent source of significant discomfort for many children with severe neurological impairment, for example, cerebral palsy and neurodegenerative conditions, and often predates the involvement of palliative care. Management therefore requires collaboration and optimal use of non-pharmacological strategies and non-opioid medications before specific therapies needing specialist skill (i.e. surgical intervention, botulinum toxin, intrathecal drug delivery) are introduced.

Opioids should remain in consideration with anecdotal success reported by paediatric palliative care physicians in treating some children with opioids for severe chronic pain secondary to muscle spasm. A recent descriptive practice survey (Slater et al., 2010) appears to confirm the viability for using opioids in children with non-malignant conditions. However, regard must be given to the potential for children with non-malignant conditions to survive for

many years and there should be regular review of the effectiveness of any opioid prescribed. Although anecdotal practice supports the use of opioid prescribing in children with non-malignant disorders, trial withdrawal of long-term opioids should be considered on a regular basis as the cause for the spasm may dissipate with time. Further information on the management of muscle spasm is available in Chapter 17 (Hickman et al., this volume).

## Bone pain

Bone pain is typically a focal, deep-seated, and intense pain that a child may describe as 'boring' or 'like a drill'. The pain can start as intermittent but escalate to become constant and unremitting and may be complicated by spontaneous pain at rest and/or movement-related incident pain.

It appears to be a common symptom in children requiring palliative care and has been well documented in:

- ◆ Non-ambulatory children with chronic neurological conditions (Khouri and Szalay, 2007).
- ◆ Inherited metabolic disorders involving:
  - ◆ primary defects of structural bone proteins—osteogenesis imperfect
  - ◆ pathological involvement of bone from systemic disease—mucopolysaccharidosis (Rossi et al., 2011).
- ◆ Secondary distortion of the normal skeletal structures as an effect of systemic treatment, e.g. prolonged steroid use.
- ◆ Cancer-induced bone pain (CIBP) (Nathrath and Teichert von Lüttichau, 2009) from primary (Eyre et al., 2009), infiltrative bone marrow (Leeson et al., 1985), or metastatic disease or as a result of treatment (Sala and Barr, 2007).

Bone pain from chronic neurological conditions often results from low bone density for a variety of reasons and children are at an increased risk of non-traumatic fracture or fracture from minimal trauma when moved or handled (Henderson et al., 2004; Khouri and Szalay, 2007). The precise mechanism for CIBP continues to be debated with work implicating local inflammatory and neuropathic mechanisms as well as central mechanisms.

## Management

The effective management of bone pain relies upon an individualized response tailored to the identified cause(s) and the child's clinical condition, life expectancy, and quality of life. As previously discussed, non-pharmacological methods and the WHO approach remain relevant.

Specific treatment involves using bisphosphonates while CIBP may require additional approaches.

### Bisphosphonate therapy

There is extensive experience in bisphosphonate therapy in children with congenital and acquired forms of osteoporosis (Batch et al., 2003; Kotecha et al., 2010) with them appearing to be not only effective but safe, even with prolonged use (Bachrach et al., 2010; Henderson et al., 2002; Howe et al., 2010). In contrast use in adults has focused on treatment of painful metastatic malignant disease (Fulfaro et al., 1998) and malignant hypercalcaemia.

Bisphosphonates are analogues of inorganic pyrophosphate, a natural inhibitor for the formation of calcium phosphate crystals, and directly reduce bone resorption (Fleisch, 1998). This is achieved by

decreasing recruitment and function of osteoclasts and direct binding to hydroxyapatite crystals in bone, making it more resistant to resorption. They are available in intravenous and oral forms with second-generation aminobisphosphonates like alendronate and pamidronate and third-generation agents such as ibandronate and zoledronic acid in regular use. Intravenous pamidronate has been the most frequently used agent, but intravenous clonidronate, ibandronate, alendronate, and zoledronate have all been shown to be as effective in cancer induced bone pain in adults and are often preferred as they are infused over a shorter time (15 min; Wardley et al., 2005).

Common side effects of bisphosphonate infusions include transient flu-like symptoms that occur 24 to 48 h after the first treatment but usually not in subsequent infusions and injection site reactions. The symptoms may be improved by prophylactic use of paracetamol or ibuprofen. Hypocalcaemia is an uncommon problem occurring within 72 h of infusion but this can be prevented by a daily intake of 1 to 1.5 g calcium. Renal toxicity is also a reported concern manifesting in patients with existing renal compromise.

Long-term adverse effects of osteonecrosis of the jaw (ONJ) and ocular inflammation have been reported. ONJ appears to be isolated to adults with cancer with recent studies (Baillargeon, 2011; Khan et al., 2008) concluding there was insufficient evidence to confirm a causal link between low-dose bisphosphonate use in the osteoporosis patient population and ONJ; the majority of children receive bisphosphonates for osteoporosis.

### Other approaches for CIBP

Treatment of CIBP can require additional approaches such as radiotherapy to the painful site, procedures that immobilize bone particularly when associated with a fracture, and in some selected cases the use of radioisotopes and other minimally invasive techniques.

### Radiotherapy

Radiotherapy plays an important role in the palliative treatment of bone metastases and remains the treatment of choice for localized disease (Falkmer et al., 2003; Hoegler, 1997; Steenland et al., 1999). This applies even to relatively radio-resistant tumours as a small reduction in the size of the lesion can have a significant modulating effect on pain. There are limited studies on the effectiveness of palliative radiotherapy in children but those that have been done are convincing (Causa et al., 2011; Deutsch and Tersak, 2004; Gibbs et al., 2006).

The delivery of single fractions or short courses of radiotherapy are generally well tolerated by children. The acute toxicities are few and may include local erythema, pain, and itching at the site and the occurrence of nausea, vomiting, and tiredness. Revision of the child's opioid dose may be required as pain abates. Long-term toxicity is not a consideration given the child's prognosis.

### Radiopharmaceuticals and interventional radioablative techniques

Radioactive bone-seeking agents are preferentially absorbed at areas of high bone turnover such as metastatic sites and are generally considered in the earlier stages of multisite disease, rather than being a last resort treatment. Several different radiopharmaceuticals are available with strontium-89 and samarium-153 approved and in common use. Evaluation in adult patients has indicated that radiopharmaceuticals are effective in reducing pain and analgesic requirements and improving quality of life. The onset of analgesia is within days to weeks and the duration of action varies according to the extent of metastatic bone disease. As such, it is not recommended in those with a life expectancy of less than approximately 4 weeks.

Different image-guided percutaneous techniques such as ablation, radiofrequency ionization, and cementoplasty can be used separately or in combination for palliation of symptoms in patients with primary or metastatic bone tumours. The therapeutic goal is managing pain through reduction in tumour volume, prevention and/or treatment of pathological fractures and decompression/debulking of bone tumours, specifically those protruding into the spinal canal. These treatments are gaining popularity in adult palliative medicine and several studies have shown success in lytic lesions refractory to conventional therapy (Belfiore et al., 2008; Thanos et al., 2008). Even newer treatment modalities such as magnetic resonance-guided focused ultrasound (Lieberman et al., 2009) have been reported to offer safe, non-invasive, and clinically effective palliation of bone metastases.

## Cancer pain

Cancer pain is detailed by Hickman et al. (Chapter 17, this volume) and further discussion relates specifically to palliative care. Progressive cancer usually results in increasing illness burden and a myriad of complex and challenging symptoms with the evidence showing pain to be a distressing and prevalent symptom towards the end of life in children with this disease (Heath et al., 2010; Pritchard et al., 2008). In a recent study of 141 parents of children who died of cancer, more than 10% considered hastening their child's death; this was more likely if their child was in pain (Dussel et al., 2010). Anticipation and continuous planning of analgesic need is crucial to effective management particularly with the drive in many countries to provide as much care as possible outside of the hospital environment.

As disease progresses the goals of care alter to maximize quality of life and minimize invasive treatments and procedures. Diagnoses regarding pain aetiology are based upon knowledge of disease pathology and clinical signs with minimal imaging and, frequently, the anticipation of pain or the assumption that pain must be present, particularly in the non-verbal child.

Not infrequently palliative chemotherapy may be offered in the hope of slowing disease progression and improving symptoms (Farah et al., 2011; Pui et al., 2011) but there is little solid evidence to show that it improves analgesia. There is clear data; however, that palliative radiotherapy with locally advanced disease can improve analgesic requirements, particularly when it is offered in combination with other treatment modalities (Bhasker et al., 2008; Hechler et al., 2008).

Decision-making regarding palliative chemotherapy is complex. It is important to understand and acknowledge the multidimensional complexities surrounding these issues when considering additional treatments. One study has shown cancer-directed therapy at the time of death to be rated negatively by parents (Hechler et al., 2008). In contrast, a prospective study showed that parents strongly favoured aggressive treatment in the palliative phase compared with health professionals and ranked hope as a more important factor for making decisions about treatment (Tomlinson et al., 2011).

There is increasing experience with anaesthetic or neurosurgical analgesic options, for example, epidural/intrathecal infusions or neurolytic blocks, when systemic analgesia has failed (Whyte and Lauder, 2012).

Epidural and peripheral nerve catheters can be used successfully despite typical contraindications (thrombocytopenia, fever, spinal

metastasis, vertebral fracture) and does not preclude patients from being cared for in their preferred setting (Anghelescu et al., 2010).

Polypharmacy and continual addition or increment of medication, without consideration for withdrawal or efficacy of drugs, should be avoided. Of particular concern can be the phenomena of opioid-induced hypersensitivity (OIH). This may well go unrecognized and is significantly under reported in children in the literature (Hallett and Chalkiadis, 2012; Heger et al., 1999).

OIH is most broadly defined as a state of nociceptive sensitization caused by exposure to opioids. The state is characterized by a paradoxical response whereby a person receiving opioids for the treatment of pain may become more sensitive to pain and is thought to be due to neuroplastic changes in the central and peripheral nervous system (Chu et al., 2008). It is important to note that OIH and analgesic tolerance are two distinct pharmacological phenomena that can result in similar net effects on opioid requirements. However, increasing the dose of opioid in OIH will paradoxically aggravate the problem and worsen the patient's pain. Considerable diagnostic confidence is required to reduce the opioid consumption in a child with end-stage cancer. It is therefore recommended to rotate the opioid, potentially in combination with a N-methyl-D-aspartate (NMDA) receptor antagonist (Laulin et al., 2002; Mercadante and Arcuri, 2005; Sjøgren et al., 1994) and methadone has been reported to have efficacy in reducing high-dose OIH (Axelrod and Reville, 2007).

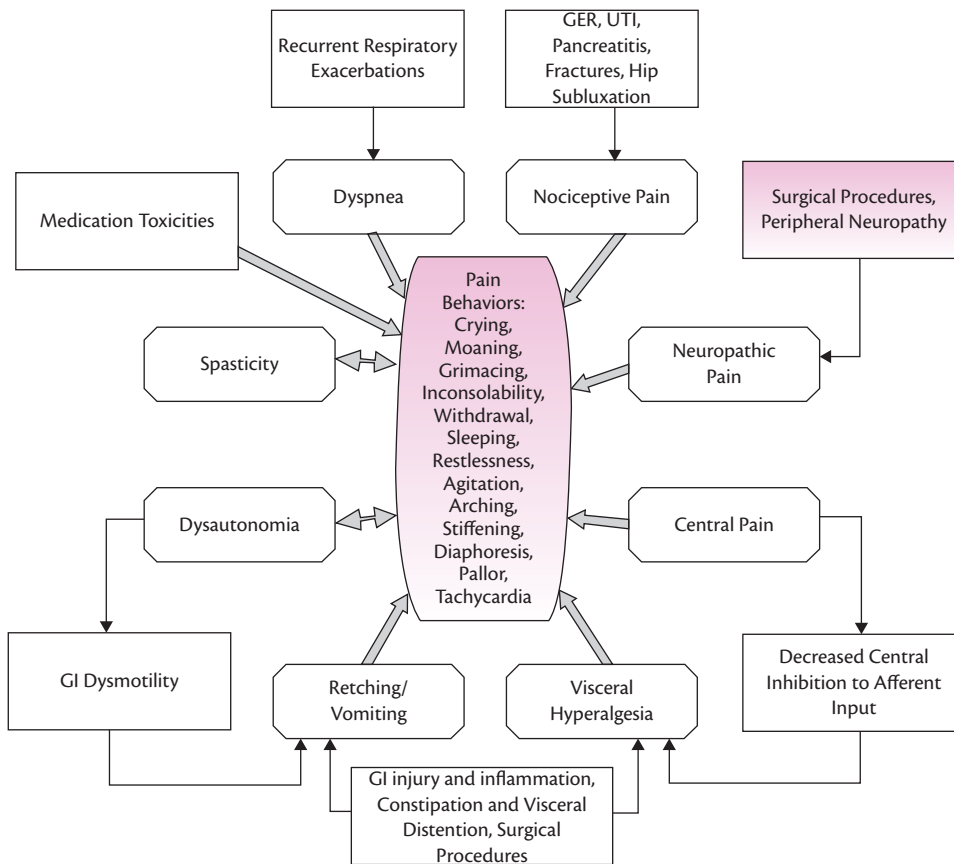

## Cerebral irritation

Cerebral irritability is a term used to describe the clinical presentation of persistent, unremitting agitation and distress. In the paediatric palliative care setting it is most often associated with the non-verbal child with severe neurological impairment or the child with progressive, often neurodegenerative disorders such as adrenoleucodystrophy or AIDS encephalopathy and, occasionally, towards the end of life in children with malignancy. At the end of life most causes can be anticipated and planned for, such as hypoxia in respiratory failure or cerebral haemorrhage in bleeding disorders or brain tumours. Cerebral irritability may also be confused with an agitated delirium at the end of life although clinical management, at this stage, is very similar.

It is a commonly held belief that cerebral irritability in the neurologically impaired child, in the absence of new pathology, is due to an abnormal brain, and abnormal neurological processing (Klick and Hauer, 2010) and it can be difficult to know whether the child is experiencing pain. Morally and ethically, the assumption has to be that *pain is a feature of this condition* until proven otherwise.

Clinically, for most of these children behaviour deviates from their known non-distressed baseline and cerebral irritability can mimic previous pain behaviours for which a cause has been found (Breau et al., 2001; Stallard et al., 2002). Several papers have acknowledged that pain of unknown cause is often severe in children with impaired cognition (Breau et al., 2003; Hauer, 2010; Hauer et al., 2007).

The classical symptom in an infant or non-verbal child with severe neurological impairment is an unrelenting, high-pitched scream. However, a diverse range of pathologies can portray similar neurological pain-related behaviours (Figure 28.1) resulting in the child's distress. If symptoms present as an acute change in behaviour, a full medical review may be required with appropriate investigations to identify the aetiology and exclude a reversible cause. However, in the neurologically impaired child, the cause often

**Figure 28.1** Potential sources of pain behaviour in children with severe neurological injury. Reprinted from *Pediatric Palliative Care*, Volume 40, Issue 5, Jeffrey C. Klick and Julie Hauer, Current Problems in Pediatric and Adolescent Health Care, pp. 120–151, Copyright © 2010, with permission from Elsevier, <http://www.sciencedirect.com/science/journal/15385442>.

remains undefined and the behaviour frequently evolves with the condition and becomes a chronic pattern bringing about a significant burden for parents and carers with ensuing exhaustion and a sense of demoralization. Several hypotheses exist for this situation with two, central neuropathic pain and visceral hypersensitivity, well supported.

### Central neuropathic pain

Central pain is a growing area of interest as improved understanding of pain pathways and processes makes it probable that it exists in infants and children with both non-malignant and malignant conditions.

#### Case example

A 13-year-old girl with early onset Huntington's chorea is persistently distressed whilst having her hair brushed or her head touched. Her parents are convinced that this response and her disordered sleeping are pain related. Examination, on multiple occasions, reveals a consistent behavioural distress to both brush and cold sensation testing over the scalp. Magnetic resonance imaging indicates bilateral lesions in the basal ganglia consistent with juvenile Huntington's chorea and a diagnosis of *central pain* is presumed. The girl was treated with and responded well to amitriptyline.

A recent definition suggests central neuropathic pain is 'pain arising as a direct consequence of a lesion or disease affecting the central somatosensory system' (Treede et al., 2008). It is triggered

by direct trauma or secondary damage by neurological disease or infection within the central nervous system (CNS) with disordered nociceptive processing at the molecular, cellular, and circuit level leading to system-wide changes in neuroexcitability that ultimately lead to central sensitization and an amplified pain experience (Hains and Vera-Portocarrero, 2011). Many metabolic, genetic, neurodegenerative, and neurological conditions in children could fulfil this definition by causing 'disease' or 'injury' of the CNS through diverse pathologies.

The concept of central pain was first introduced in 1891 (Edinger, 1891) and 15 years later, Dejerine and Roussy (1906) in their seminal paper 'Le Syndrome Thalamique', described a small case series of adult patients with a lesion in the thalamus and internal capsule causing 'severe, persistent, paroxysmal, often intolerable pain on the hemiplegic side not yielding to any analgesic treatment'. Central pain was hence termed 'thalamic pain' with the thalamus thought to play a key role, either as a generator of pain or by abnormal processing of ascending input (Craig et al., 1994; Wilkins and Brody, 1969). However, not all patients with a thalamic lesion suffered from pain and the spinothalamocortical pathway, important for temperature and pain sensibility, was also implicated (Boivie et al., 1989).

In adults the intensity of pain is reported to fluctuate and can be increased by internal or external stimuli such as stress or cold, and be alleviated by rest or distraction (Bowsher, 1996). Parallels can be found with infants and children with cerebral irritability as they have similar specific pain patterns, precipitating factors and they often respond well to sleep and sedation and, in some cases, distraction methods.

Strictly speaking, the newly proposed grading system to diagnose this condition requires a history suggestive of a relevant lesion, the presence of pain with a distinct sensory distribution in a corresponding body part, indication of negative or positive sensory signs within the area and confirmation of the lesion by a diagnostic test (Treede et al., 2008). Unfortunately, many children and infants with a possible diagnosis are not able to communicate making it very difficult to elicit sensory changes. However, if sensory disturbances like allodynia or dysaesthesia are consistently present then a strong indicator for central neuropathic pain is present.

The other challenge for paediatric clinicians caring for a non-verbal child with severe neurological impairment is that these children often have assorted types of pain. For instance, the complicated issue of whether spasticity is the primary cause of pain, or the result of pain from another source. Attention must be given to exploring and managing each pain type in a systematic way.

### Visceral hypersensitivity

Visceral hypersensitivity or hyperalgesia is an altered response to visceral stimulation resulting in activation of pain sensation and has been regarded as a cause of functional gastrointestinal disease (Delgado-Aros and Camilleri, 2005). A recent review by Woolf reports that visceral pain hypersensitivity syndromes in the digestive system looks to have a component of central sensitization which is dynamically maintained by input from the gastrointestinal system (Woolf, 2011).

Gastrointestinal pain is commonly reported in children with severe cognitive impairment (Hauer, 2010; Hauer et al., 2007; Houlihan et al., 2004; Klick and Hauer, 2010) and chronic cerebral irritability in this group is often temporally related to gastrointestinal symptoms and signs including feed intolerance, flatus, retching, vomiting and pain. Development is thought to result from repeated painful gastrointestinal experiences in infancy; it is an outcome of sensitization not the underlying neurological injury. The consequence of these painful experiences is recruitment of previously silent nociceptors and sensitization of peripheral visceral afferent fibres causing pain (Hauer et al., 2007; Zangen et al., 2003). Such experiences might include a history of prolonged neonatal care, gastro-oesophageal reflux, constipation, gastrostomy feeding and fundoplication. Visceral pain has also been associated with motor abnormalities of the gut, exaggerated intraluminal pressures and pain sensation and an important factor in pain generation appears to be the presence of nociceptors in the gut wall that can be activated by a variety of modulators at lower, normally ineffective, intraluminal pressures (Buéno et al., 2000).

### Management

Children with cerebral irritability present with their own individual narrative, symptoms, and signs. The most important step in the management is to obtain a detailed history and evaluation. In the case of chronic cerebral irritability, it may be necessary to request a symptom diary to establish temporal factors and understand the impact upon the child and family. This should be followed by the relevant investigations to exclude all other possible causes of pain and irritability. Treatment is then directed at the identified cause.

Pharmacological management directed at central neuropathic pain and visceral hypersensitivity has been poorly studied and, in adults, central neuropathic pain has been classically difficult to treat (Klit et al., 2009). Approaches with medication would usually involve a trial of adjuvant agents including tricyclic antidepressants,

anticonvulsants, and NMDA receptor antagonists (Davis et al., 2009; Hauer et al., 2007; Zangen et al., 2003).

The paucity of paediatric data on this topic is striking considering the regular prescribing of anticonvulsants in paediatric practice. A single case report of a 3-month-old infant with neurological impairment and cerebral irritability detailed improvement in tone and disposition after the infant was treated with 5 mg/kg gabapentin at night following the failure of regular lorazepam and intermittent morphine to provide relief. Gabapentin was well tolerated and dose increases lead to further improvement (Behm and Kearns, 2001).

Opioids are not a first-line medication in this situation although they have been shown to improve pain in some central neuropathic pain conditions (Attal et al., 2010; Dworkin et al., 2007). They may be appropriate as a short-term control measure for acute neuropathic pain until other agents have been introduced and titrated to effect (Barrera-Chacon et al., 2011; O'Connor and Dworkin, 2009; Rowbotham et al., 2003). However, as the use of any analgesic medication for children with cerebral irritability may be necessary for a prolonged period of time the potential for long-term effects of using the medication must be given due consideration. In the case of a long-term opioid the development of tolerance or opioid-induced hyperalgesia is a concern. Despite these measures some children will have intractable symptoms and may require additional medications such as benzodiazepines, phenobarbitone, or agents such as levomepromazine and haloperidol.

Neural stimulation therapy including motor cortex stimulation (Fontaine et al., 2009), deep brain stimulation (Owen et al., 2006), and transcranial magnetic stimulation (Leung et al., 2009) have been reported to be successful in adults with treatment resistant central pain. There are no reports of any of these methods being used in children; however, the use of cortical brain stimulation is well established in children with refractory epilepsy and has a good therapeutic and safety profile.

### Neuropathic pain

The cause of neuropathic pain is very dependent on the disease process and is often related to compression, direct invasion, or infection of the peripheral nerves or spinal cord and is detailed further in this volume by Walker (Chapter 21) and pharmacological treatment is described by Rastogi and Campbell (Chapter 48). In palliative care for children the mainstays of therapy involve the use of opioids and adjuvant analgesics. Although neuropathic pain is more likely than other types of pain to be partially or wholly opioid resistant (Collins et al., 1995), opioid responsiveness cannot be reliably predicted in individual patients solely on the basis of the type of pain (Cherny et al., 1994). Therefore, a trial of opioid therapy should not be withheld or limited solely on the basis of inferred pathophysiology.

### Intractable pain

Palliative sedation in end of life care is an accepted but controversial means of providing relief from otherwise refractory and intolerable symptoms and distress (Chater et al., 1998; Manzini, 2011). The European Association for Palliative Care defines palliative sedation as the monitored use of medications intended to induce a state of decreased or absent awareness in order to relieve the burden of otherwise intractable suffering in an ethically acceptable manner (Cherny et al., 2009). The use of sedation in the setting

of refractory pain assumes that all possible analgesic therapies have been employed and that there is no acceptable means of providing analgesia without compromising consciousness (Collins, 2010).

There is a considerable lack of information regarding palliative sedation in paediatrics; there are no international guidelines for children and little is known about the clinical effectiveness of sedation practice. A recent review of the paediatric literature offers some insight into practice by stating that sedation in children remains controversial and is influenced by educational, cultural, legal, moral, and health policy issues. Importantly, it highlighted that physical symptoms are described as an indication for practice but existential suffering must also be considered in the evaluation of refractoriness of symptoms (Kiman et al., 2011). Existential suffering of parents must also be acknowledged, as their distress behaviour may impact upon patient management and this was explored in the study by Dussell et al. (2010).

Reports of pain and suffering at the end of life are mainly described for children with end-stage cancer, but also recognized in HIV/AIDS (Bennett and Givens, 2011; Collins, 1995). Recent studies have shown that incidence may be higher than perhaps expected. A retrospective case series of children with end-stage cancer showed that 25 of 37 patients (68%) received 'palliative sedation' for unrelieved suffering, with pain being the most common symptom cited (Postovsky et al., 2007). Also, a survey (Pousset et al., 2011) of Belgian physicians signing death certificates of all children between the ages of 1 and 17 years found that continuous, deep, and persistent sedation was used in 21.8% of all deaths; 46.8% of all non-sudden deaths. Physicians had the explicit or concurrent intention of hastening death in one-quarter of cases. The incidence of continuous sedation in this study was higher than the 14.5% found in a comparable study of adults (Chambaere et al., 2010).

For the specific cohort who requires sedation for intractable pain, recommended therapeutic modalities include opioids, benzodiazepines, neuroleptic and anaesthetic agents such as propofol.

## Conclusion

Managing pain is only one of the aspects of providing palliative care for children but in reality it is a core task as pain is one of the commonest symptoms experienced by dying children. It is encountered in every existential dimension and a child in severe pain cannot engage with carers in a way that allows meaningful exploration of wider fears or concerns. Even where the primary painful stimulus is physical, its perception and experience by a child will be dictated by the spiritual and psychosocial context in which it occurs. Good pain management therefore not only requires the use of appropriate analgesics but specific attention to psychosocial, cultural, spiritual, and other physical issues.

## CHAPTER 29

# Recurrent abdominal pain

Jennifer Verrill Schurman, Amanda Drews Deacy, and Craig A. Friesen

### Summary

Recurrent abdominal pain is a common complaint in children and adolescents; however, it has been historically understudied and not well understood. Recently, an improved diagnostic classification system has resulted in new research information being generated at an increasing rate. Although significant gaps in our knowledge remain, we are gradually coming to understand the complex aetiology of recurrent abdominal pain in children and are making strides in clinical treatment. However, specific clinical practice guidelines do not yet exist and evidence remains limited for most, if not all, of the common treatments employed. This chapter highlights current theory and evidence available to guide office-based assessment and intervention efforts, as well as promising directions for future research.

### Introduction

#### Epidemiology

Recurrent abdominal pain has long been acknowledged to be one of the most common chronic pain entities in children. However, only recently has it been recognized as a global health problem. The prevalence has been estimated at 0.3% to 19% (median 8.4) in Western populations (Chitkara et al., 2005), with similar rates recently documented worldwide and including developing countries (Devanarayana et al., 2011; Zhou et al., 2011). Prevalence appears to peak in early school-age (4–6 years) and preadolescent children, with females somewhat overrepresented at older ages (Chitkara et al., 2005). Abdominal pain can persist for years with many children continuing to have problems with both abdominal pain and associated symptoms into adulthood (Gieteling et al., 2008).

#### History

In the late 1950s, Apley and Naish first described the entity which became known as recurrent abdominal pain of childhood or 'RAP' (Apley and Naish, 1958). RAP was described as three or more bouts of pain severe enough to affect activities that occurred over a period of at least 3 months. Less than 10% of the patients evaluated by Apley and Naish were determined to have an organic aetiology for their pain. Given the lack of diagnostics available during that time, it is likely that some children with organic disease were included under this heading. Even more important, children with a wide variety of clinical presentations and aetiologies were lumped under the single clinical 'diagnosis' of RAP. RAP was so inclusive as to be

rendered useless to guide diagnosis or treatment. In recent years, there has been increasing effort to redefine RAP into more distinct groups to guide research and clinical decision-making. Continuing work began in 1990, the Rome II working group established discrete diagnostic criteria for several functional gastrointestinal disorders (FGIDs) in children (Rasquin-Weber et al., 1999). These were revised to the current Rome III diagnostic criteria in 2006 (Rasquin et al., 2006). As defined by the Rome criteria, the FGIDs are a set of diagnoses with specific symptom profiles in the absence of structural or biochemical abnormalities to explain the symptoms. FGIDs related to chronic or recurrent abdominal pain include irritable bowel syndrome (IBS), functional dyspepsia (FD), functional abdominal pain (FAP), and abdominal migraine (see Box 29.1 for symptom-based criteria). Both the American Academy of Pediatrics and the North American Society for Pediatric Gastroenterology, Hepatology, and Nutrition have supported this shift in diagnostic classification, calling for the term 'RAP' to be retired in 2005 (Di Lorenzo et al., 2005a). Although the Rome criteria have not been fully validated, there is evidence that the great majority of children who would have formerly been diagnosed with RAP meet criteria for at least one FGID, with IBS and FD being the two most common (Schurman et al., 2005; Walker et al., 2004). Although clinical experience would support the utility of Rome criteria, this utility has yet to be established in well-designed research studies. In addition, there is variability in how the Rome criteria are applied and the definition of 'organic disease' is not universal (Chogle et al., 2010). The diagnosis also can vary depending on who provides the history. For example, children and parents can vary greatly with regard to stool history (Schurman et al., 2005). While there is still work to be done to refine and validate the criteria, Rome III diagnoses represent the best available classification for children with recurrent abdominal pain and are the current basis for entry into most therapeutic trials.

#### Aetiology

FGIDs are probably best understood utilizing a biopsychosocial model which states that abdominal pain occurs as a result of varying contributions from, and interactions between, biological factors, psychological factors, and social factors. Each of these factors may initiate or contribute to the frequency, duration, or intensity of pain. Further, this model is dynamic; children are believed to achieve the same end result (i.e. abdominal pain) through different pathways.

**Box 29.1** Rome III symptom criteria for functional gastrointestinal disorders related to abdominal pain in children**Functional dyspepsia**

All of the following present at least once weekly for at least 2 months:

- ◆ Persistent or recurrent abdominal pain or discomfort centered in the upper abdomen.
- ◆ Pain not relieved by defecation or associated with a change in stool frequency or form.
- ◆ No evidence of an inflammatory, anatomic, metabolic, or neoplastic process to explain the symptoms.

**Irritable bowel syndrome**

All of the following present at least once weekly for at least 2 months:

- ◆ Abdominal discomfort or pain associated with two or more of the following:
  - ◆ improvement with defecation
  - ◆ onset associated with a change in stool frequency
  - ◆ onset associated with a change in stool form.
- ◆ No evidence of an inflammatory, anatomic, metabolic, or neoplastic process to explain the symptoms.

**Functional abdominal pain**

All of the following present at least once weekly for at least 2 months:

- ◆ Episodic or continuous abdominal pain.
- ◆ Does not meet criteria for another FGID.
- ◆ No evidence of an inflammatory, anatomic, metabolic, or neoplastic process to explain the symptoms.

**Abdominal migraine**

All of the following must have occurred at least twice in the preceding 12 months:

- ◆ Paroxysmal episodes of intense, acute periumbilical pain lasting at least 1 h.
- ◆ Intervening periods without pain lasting weeks to months.
- ◆ Pain which interferes with normal activities.
- ◆ Pain associated with at least two of the following:
  - ◆ anorexia
  - ◆ nausea
  - ◆ vomiting
  - ◆ headache
  - ◆ photophobia
  - ◆ pallor.
- ◆ No evidence of an inflammatory, anatomic, metabolic, or neoplastic process to explain the symptoms.

**Biological factors**

The biological factors most implicated in the generation of abdominal pain include motility disturbances, visceral hypersensitivity, and inflammation. A variety of motility disturbances have been well documented in adults with both IBS and FD. Although there are many fewer paediatric studies, the findings in children tend to parallel those in adults. IBS is associated with either rapid colonic transit typical of diarrhoea-predominant IBS (D-IBS) or delayed colonic transit typical of constipation-predominant IBS (C-IBS). However, transit is increased in only 48% of adults with D-IBS and decreased in only 20% of those with C-IBS (Camilleri and Di Lorenzo, 2012). FD has been associated with a wide array of electromechanical disturbances in adults including delayed gastric emptying, gastric electrical disturbances, impaired fundic accommodation (relaxation) with meals, and disorganized gastroduodenal motility (Timmons et al., 2004). Delayed gastric emptying and gastric electrical disturbances have each been demonstrated in approximately 50% of children with FD (Friesen et al., 2006). Symptom severity also has been correlated with delayed emptying, gastric electrical abnormalities, impaired antral motility, and impaired accommodation in children with FD (Friesen et al., 2006; Devanarayana et al., 2008, 2012; Olafsdottir et al., 2000).

Visceral hypersensitivity is believed to be of central importance in the generation of pain in FGIDs in adults with similar, but somewhat conflicting, studies in children. In adults with IBS, increased rectal sensitivity to stretch has been reported in 21% to 95% of patients (Camilleri and Di Lorenzo, 2012). Rectal hypersensitivity has been demonstrated to have a sensitivity of 89% and a specificity of 83% in identifying children with IBS (Camilleri and Di Lorenzo, 2012). However, other studies have demonstrated much lower rates of hypersensitivity with no differences between paediatric patients with IBS and FAP. In adults with FD, visceral hypersensitivity to distension has been demonstrated in 34% to 65% of patients (Timmons et al., 2004). Hypersensitivity to acid has also been reported in adults with FD (Oshima et al., 2012). Water load volume, an indicator of visceral sensitivity, has been shown to differ between children with abdominal pain (including those specifically with FD) and controls (Anderson et al., 2008; Schurman et al., 2007).

The two main inflammatory cells which have been implicated in FGIDs are mast cells and eosinophils. In adults with IBS, mast cells are increased in the ileum and colon, are more likely to be in close proximity to nerves, and are more likely to be activated when near nerves; in addition, when near nerves, their density correlates with pain severity (Barbara et al., 2006; Park et al., 2003; Santos et al., 2005). Treatment with mast cell stabilizers has been shown to decrease the visceral hypersensitivity in IBS patients (Klooker et al., 2010). Mast cell density has been shown to be increased in the stomach of adults with FD and their activation is associated with visceral hypersensitivity (Hall et al., 2003; Hou et al., 2001). Duodenal eosinophils also have been highly implicated, with density significantly increased in adults with FD (Walker et al., 2011). Treatment directed at mucosal eosinophils has been shown to decrease pain in children with FD in association with duodenal eosinophilia (Friesen et al., 2004).

**Stress response and biological factors**

Stress in various forms predisposes adults to develop IBS and increases symptoms in children with FGIDs (Katiraei and Bultron, 2011; Walker et al., 2011). Anxiety and stress appear to interact

with the gastrointestinal tract primarily through release of corticotrophin-releasing hormone (CRH) with secondary activation of mucosal mast cells. CRH mediates visceral sensitivity by activating mucosal mast cells with subsequent mediator sensitization of afferent sensory enteric nerves (Wood, 2004). An association has been reported between elevated rectal mast cells and anxiety in adults with IBS (Dunlop et al., 2002). Adults have demonstrated selective luminal release of tryptase and histamine from jejunal mast cells under cold stress; the magnitude of release was similar to that induced by allergen exposure in food allergic patients (Santos et al., 1998). The gastrointestinal response to stress can be mitigated by mast cell-stabilizing drugs (Moeser et al., 2007). An association between antral mast cell density and anxiety also has been demonstrated in children with FD (Schurman et al., 2010b).

### Psychological factors

Children with FGIDs tend to have more concurrent symptoms of anxiety and depression than their peers (Di Lorenzo et al., 2005b). Further, early temperament markers of anxiety may predict a relative increased risk for the development of FGIDs in early school-age, while children with FGIDs appear to be at increased risk for anxiety and depression in the future (Di Lorenzo et al., 2005b; Ramchandani et al., 2006). While externalizing issues (e.g. aggression, conduct problems) may present in a subset of children with FGIDs, they are certainly far less common (Schurman et al., 2008). To date, however, there is no evidence that emotional or behavioural symptoms predict symptom severity, course, or response to treatment.

### Social factors

While it is natural for parents to want to comfort their children when in pain, solicitous parenting behaviours have been found to predict prolonged illness, symptom reoccurrence, and increased disability in children with chronic medical conditions, including FGIDs (Brace et al., 2000; Walker and Zeman, 1992). Parental attention to the child's abdominal pain has been shown to increase verbal complaints in response to a water load task as compared to parental distraction; these behavioural changes were found despite children reporting similar levels of experienced pain across conditions (Walker et al., 2006). Parents of patients with FGIDs also tend to have more symptoms of anxiety and depression, as well as more physical complaints, leading to speculation that these parents may model more illness behaviour for their child, provide more attention to their child's physical symptoms, and/or bestow on the child a predisposition toward anxiety and/or gastrointestinal dysfunction (Ramchandani et al., 2006).

### Other factors

While impractical to list all possible potential contributors to an individual child's abdominal pain experience, several additional areas merit specific mention. Sleep can play a major contributing role in the maintenance of chronic pain. Pain often results in increased stress and arousal that can interfere with the quality and quantity of a child's sleep, while decreased sleep quality and quantity have been found to predict increased pain the following day (Lewin and Dahl, 1999). Disrupted sleep has been found to result in increased emotional/behavioural problems that can, in turn, lower a child's pain tolerance, interfere with effective use of coping skills, and increase functional disability (Kundermann et al., 2004). Finally, adequate sleep appears to promote tissue healing, immune function, and the body's natural analgesic efforts, which can aid in both pain relief and recovery (Lewin and Dahl, 1999).

School can be very stressful for children with learning or social problems, particularly if these are not identified and treated effectively; escape from school may be very reinforcing for these children. One study found an inverse relationship between academic ability and number of visits to the school health office for physical complaints, including 'stomach ache,' such that regular education students with lower academic ability were 4.25 times more likely to visit the health office at school than students with high academic ability (Shannon et al., 2010). Similarly, in children with IBS, a stronger relationship between symptoms and disability has been documented for girls with lower perceived social competence and for boys with lower perceived athletic competence (Claar et al., 1999). More broadly, life event stress has been found to be higher in children with FGIDs, and the relationship between daily stressors and physical complaints is stronger, than in healthy control peers (Di Lorenzo et al., 2005b).

Even areas of difficulty that are clearly consequences of pain, arising secondary to pain onset, are important to consider in evaluation and treatment, as they may ultimately play a contributory role in pain maintenance and/or escalation. Functional disability is one such area. Children with frequent abdominal pain are at increased risk for social isolation and school absenteeism (Youssef et al., 2008). Children with FGIDs report quality of life lower than healthy peers and similar to that of children with inflammatory bowel disease (Youssef et al., 2006). However, recent research has highlighted the reciprocal nature of the relationship between pain and disability. While pain and disability are associated cross-sectionally, cutting back in normal daily activities on the current day appears to increase the subjective experience of pain and the likelihood of further activity cutbacks on the subsequent day (Schurman et al., 2011). Ultimately, over time, this may lead to an escalating cycle of pain and disability.

## Implications for care

### Evaluation

To date, no evidence-based guidelines exist for the evaluation of chronic abdominal pain, in general, or for any specific FGID related to pain in children. Currently, the presence of alarm signs and symptoms are accepted as indicators of potential organic disease and indications for further evaluations (Table 29.1). In the presence of alarm symptoms, blood tests, radiological evaluation, and endoscopy are reasonable evaluations and some recommendations are included in Table 29.1. In the absence of alarm symptoms, it is reasonable to make a diagnosis of a FGID without performing testing initially. In general, there is insufficient literature regarding the utility of any specific diagnostic tests in children with chronic abdominal pain including blood tests, ultrasound, or endoscopy (Di Lorenzo et al., 2005b). Despite the lack of studies, blood tests and endoscopy remain the most commonly performed 'standard' tests in the evaluation of dyspepsia in children in paediatric gastroenterologist practice (Schurman et al., 2010a). Ultimately, most children with chronic abdominal pain probably will not have an identified specific disease accounting for their symptoms. However, as discussed in the context of the biopsychosocial model, this does not mean that there are not biological contributors to the patient's pain. In fact, it is likely that there are biological contributors in the majority of cases and that, even in patients where symptoms are driven primarily by anxiety or stress (if we had a means to make

**Table 29.1** Alarm signs and symptoms for chronic or recurrent abdominal pain with suggested initial workup

Signs/symptoms	Initial evaluation
1. Weight loss	CBC, albumin, ESR, CRP, and coeliac serology
2. Deceleration of linear growth	
3. Delayed puberty	
4. Significant vomiting	LFTs, amylase, lipase, UA, and abdominal ultrasound
5. RUQ pain/tenderness	
6. Haematemesis or haematochezia	CBC, ESR, CRP, coeliac serology, stool exam for pathogens, and endoscopy
7. RLQ pain/tenderness	
8. Chronic severe diarrhoea	
9. Perianal disease or oral lesions	
10. Systemic symptoms including unexplained fever, unexplained rash, or arthritis	
11. Family history of IBD or coeliac disease	
12. Dysphagia	Barium swallow and endoscopy

CBC = complete blood count; CRP = C-reactive protein; ESR = erythrocyte sedimentation rate; IBD = inflammatory bowel disease; LFT = liver function test; RLQ = right lower quadrant; RUQ = right upper quadrant; UA = urinalysis.

that determination), there is a biological pathway which translates the central stress response into gastrointestinal symptoms. It seems likely that, in the end, the value of testing will not be in making a diagnosis of an 'organic' disease but in identifying the biological factors (e.g. mucosal inflammation, dysmotility, and/or visceral hypersensitivity) contributing to the generation of symptoms and which might be amenable to specific treatments. This may account for recent findings that endoscopy results in a change in management in two-thirds of children with abdominal pain (Thakkar et al., 2011).

Identification of psychosocial factors that may be contributing to symptom generation, and that may be appropriate targets of treatment, also is pivotal as part of the initial clinical workup. To that end, brief self- and/or parent-report measures can be employed within a busy clinical setting to quickly screen for areas of concern and prioritize treatments as part of the initial clinical approach. Many validated questionnaires are available to assess issues common in children with FGIDs, such as psychological functioning, parent behaviour, sleep, and functional disability, among others (see supplementary material online for a list of questionnaires to consider by area). In addition, relevant information about school (e.g. attendance, perceived barriers, learning history) may be elicited quickly via a few targeted questions posed during the medical history.

## Treatment

To date, no evidence-based guidelines exist for the treatment of chronic abdominal pain, in general, or for any specific FGID-related to pain in children. The current emphasis is on treating

simultaneously as many of the identified biopsychosocial contributors as possible, with the belief that this provides the best opportunity to effectively break the pain cycle. In addition, the importance of early intervention cannot be overstated given the potential long-term consequences of functional disability on academic, social, and emotional development in children and adolescents. The following presents a stepped approach to care, beginning with what may be realistically accomplished within the primary care office setting, moving through referral for subspecialty collaboration, and ending with more intensive rehabilitation models for treatment.

## Education and reassurance

Education is a vital foundational component of basic in-office care for children with FGIDs. Providing a clear explanation of FGIDs—including the reassuring messages that the child's pain is understood, that it is not dangerous, and that there is something that can be done about it—can be very helpful in decreasing anxiety and further healthcare seeking in both the parent and child (Di Lorenzo et al., 2005a). Further, clearly communicating the biopsychosocial nature of FGIDs helps provide a context for the multicomponent approach to treatment, thereby improving patient/family willingness to adhere to the recommended treatments and setting the stage for acceptance of later subspecialty referrals, if needed. In fact, there is some evidence that children whose parents accept a biopsychosocial conceptualization of abdominal pain and its treatment are more likely to experience symptom improvement (Scholl and Allen, 2007).

## Medication

While education and reassurance are universal, medication management varies by specific FGID. However, evidence for most of the current medications in use has been obtained from studies in adults; only a small number of controlled studies in children currently exist.

In adults with IBS, tricyclic antidepressants (TCAs), selective serotonin reuptake inhibitors (SSRIs), and antispasmodics (including cimetropium/dicyclomine, peppermint oil, pinaverium, and trimebutine) targeting visceral hypersensitivity and/or dysmotility, but not bulking agents, are effective (Ford et al., 2009; Ruedert et al., 2011). There have been only two controlled paediatric trials assessing TCAs for FGIDs and no trials for SSRIs. Amitriptyline was ineffective in the larger trial which included FD, FAP, and IBS patients (Saps et al., 2009). In the other trial, which included only IBS patients, amitriptyline treatment was associated with decreased diarrhoea and pain (Bahar et al., 2008). Other than a single trial of peppermint oil, there are no controlled trials of antispasmodics in paediatric IBS (Kline et al., 2001). It appears that fibre has no significant effect on pain in children with IBS (Huertas-Ceballos et al., 2009). Antibiotics have been shown to be effective for non-constipated IBS in adults, but have not been evaluated in children (Basseri et al., 2011). Two controlled studies support the use of probiotics (*Lactobacillus rhamnosus* GG) in children with IBS (Francavilla et al., 2010; Gawrońska et al., 2007). Reasonable initial options based on the existing evidence would include daily low-dose TCAs (e.g. amitriptyline; 0.3 mg/kg given at bedtime) with antispasmodics (e.g. dicyclomine or peppermint oil) given on an as-needed basis, antibiotics directed at small bowel bacterial overgrowth (e.g. metronidazole or rifaximin), or probiotics for diarrhoea-predominant IBS and a laxative with an SSRI for constipation-predominant IBS.

Seventy-two per cent of paediatric gastroenterologists treat FD empirically (before endoscopy) with acid reduction therapy (Schurman et al., 2010a). H2 antagonists, proton pump inhibitors (PPIs), and prokinetics have been found to be superior to placebo in the treatment of FD in adults (Moayyedi et al., 2006). Only one small trial of acid suppression has been published in paediatric FD, in which famotidine was shown to be superior to placebo in global pain resolution (See et al., 2001). Prokinetics have not been evaluated for FD in children. Reasonable initial options based on the existing evidence would be an H2 antagonist or a PPI (especially if there are reflux symptoms) when pain is the predominant symptom or a prokinetic agent targeting dysmotility when pain is not the predominant symptom (e.g. more problems with nausea or bloating).

Outside of IBS and FD, there are two other controlled trials involving pain-associated FGIDs in children. Cyproheptadine was found to improve intensity and frequency of pain in children with FAP (Sadeghian et al., 2008). Pizotifen, which is not approved in the US, has been demonstrated to have efficacy in the treatment of abdominal migraine (Symon and Russell, 1995). Frequently prescribed medications for abdominal migraine include propranolol, cyproheptadine, and sumatriptan though these have not been evaluated in controlled trials in children.

Regardless of FGID, inflammation with eosinophils and/or mast cells represents a potential therapeutic target. Inflammation may be documented (e.g. duodenal eosinophils in FD) or suspected based on clinical profile (e.g. mast cells in an anxious D-IBS patient). Montelukast has been shown to be effective in children with FD in association with duodenal eosinophilia (Friesen et al., 2004). Other options targeting eosinophils and mast cells include combination of H1 and H2 antagonists (e.g. ranitidine and hydroxyzine) and oral cromolyn as a mast cell-stabilizing agent (Friesen et al., 2006; Stefanini et al., 1995).

### Behavioural coaching

Parental education and skills training is a critical component of in-office care of chronic abdominal pain patients. Parents can be coached to maintain behavioural expectations for their child's participation in school and other activities (Scholl and Allen, 2007). Participating in normal daily activities, even when in pain, gives children a sense of control over the pain; as children feel more in control, anxiety (and the associated stress response) often will decrease. It is important to note that while some form of daily activity is critical to long-term health and recovery, overdoing it can complicate and prolong the symptom course. Emphasis should be placed on preventing further declines in functioning and on gradually and systematically increasing daily expectations from whatever point the child is currently. Parents should be taught to encourage and model good coping with pain symptoms (Scholl and Allen, 2007). Parents can gently remind and encourage children to use skills like deep breathing, distraction, relaxation, positive thinking, etc. during pain episodes, or before events that seem to trigger pain (e.g. eating, going to school, having a test). Parents can be encouraged to provide attention and praise (or other rewards) for children's demonstration of good coping and/or well behaviours (e.g. using relaxation, attending a portion of the school day), and to ignore and minimize attention paid to symptom complaints and non-verbal pain behaviours (Crushell et al., 2003). Related to this, providers can reassure parents that it is okay, and indeed preferable, not to regularly inquire about their child's pain. Pain is worse when children pay attention to it and better if they are distracted from it

(see supplementary material online for a handout covering a variety of behavioural coaching points).

### School accommodation

Many children with chronic abdominal pain have school problems. They may miss school days (or even weeks) because of symptoms, doctors' visits, or hospitalizations. They also may get behind in daily school work, have a hard time paying attention in class, suffer social embarrassment related to frequent trips to the toilet, or feel overwhelmed by makeup work. Accommodations that can be helpful in terms of supporting patients' success at school and encouraging their regular attendance include: allowing easy access to the toilet, encouraging brief breaks for use of stress and pain management skills, allowing participation in clubs and sports while working on getting back to school, and carefully considering makeup work and the timeline for its completion. Helping families initiate a formal plan according to local regulations (e.g. Section 504 Plan in the US, Educational Statement in the UK) for a patient's health issues can be beneficial to formalize these accommodations and encourage consistent participation across all school staff. Additionally, when children have been out of school for a long period of time due to their abdominal pain and/or other physical symptoms, a gradual and structured return to the classroom may be an important part of the treatment plan. Approaching return to school in this fashion has the advantage of reducing patients' fear and avoidance, while reintegrating patients into age-appropriate academic/social activities and redirecting attention from symptoms toward functioning (Walker, 2004; Walker et al., 2009). Balancing demands with support is vitally important, as stress can increase pain and have an overall negative effect on the recovery process. Although variations on a graduated approach to school re-entry likely exist, the three key steps include: (1) choosing a block of time the patient is able to attend every day without increased symptoms, (2) the patient attending school for the agreed upon amount of time (no more, no less), regardless of pain, and (3) regularly evaluating the patient's progress to determine when and how much additional class time to add (see supplementary material online for a sample approach).

### Collaboration with ancillary services

For a subset of children, in-office care will be insufficient to resolve the child's pain and/or disability. When this occurs, it may be helpful to refer the child for additional subspecialty treatment as part of the comprehensive treatment package. Maintenance of regular follow-up in the primary care office is vital, as is close collaboration with any subspecialty providers involved to ensure ongoing coordination of care and consistency of messages to the family. Some of these subspecialty services have an evidence base to support their use in children with FGIDs, while others are based on more theoretical or practical concerns.

The three ancillary services with the most, albeit still limited, empirical support are cognitive-behavioural therapy, hypnotherapy, and biofeedback-assisted relaxation training (BART; Brent et al., 2008). All three services, as applied to FGIDs, focus on changing thoughts and/or behaviours in the interest of alleviating physical symptoms. While these services also may help with subclinical anxiety, they primarily target pain management and behavioural activation; they are not geared to address major mental health disorders. When referring out for these services, it may be helpful to communicate expectations directly to the collaborating provider prior to, or at the onset, of care. Often, children

with FGIDs do not have a diagnosable mental health disorder. As such, community providers without specific paediatric or health psychology training may not be certain of their role in the treatment plan and/or may not be experienced enough to know how to initiate treatment.

Certainly, when more substantial mental health issues are apparent, referral for individual therapy, psychiatry, and/or family therapy may be helpful. Even if these issues have arisen secondary to the onset of pain, mental health issues can be a significant source of emotional and social stress that may play a further contributory role in maintenance of pain and disability. Similarly, psychoeducational evaluation of learning issues may be helpful for a subset of children who have a history of academic performance concerns. More subtle learning issues may not be diagnosed until later in elementary school or beyond, as workload demands increase and exceed the individual's ability to compensate.

In some cases, in which children have been physically inactive for a prolonged period of time, or are resistant to increasing physical activity and engagement, a brief course of physical therapy may be beneficial to increase muscle tone, flexibility, and/or stamina. A home exercise plan based on the child's current level of physical conditioning and the desired activity goal (e.g. walking around the school building without difficulty, return to competitive sports) can be helpful in structuring the child's physical rehabilitation, as well as providing parents with tangible daily expectations that may be built into the behavioural contingency plan. Other alternative treatments, such as therapeutic massage and acupuncture, also may be beneficial in a subset of children with FGIDs to promote pain relief and recovery of function. Again, referral for many of these treatments will be based purely on practical concerns related to a given child, including the perceived acceptability of one treatment versus another, as the evidence base remains quite limited.

### Intensive outpatient/inpatient rehabilitation

In the event that coordinated outpatient treatment as already described is not sufficient—that is, a child continues to experience significant pain symptoms and, more importantly, continues to suffer precipitous declines in his or her functioning—a higher level of treatment may be needed. Intensive day treatment or inpatient pain rehabilitation programmes may represent a useful model of care in these cases. Such programmes typically utilize all of the modalities previously described, albeit in a more structured, controlled environment to help patients and their parents to 'walk the walk' in real time and in the context of a supportive, therapeutic environment. The ultimate goal for these patients is to return to their homes, schools, and friends and transition back to their outpatient care team for monitoring and building upon gains made.

Unfortunately, only a few, uncontrolled studies have examined the effectiveness of such programmes. Results from three prospective studies of two different 3-week multidisciplinary inpatient programmes for paediatric chronic pain suggested improvements in pain intensity, pain-related disability, and school attendance, as well as in patients' emotional distress and pain-related coping (Eccleston et al., 2003; Hechler et al., 2009, 2010). A recent retrospective review of an inpatient paediatric pain treatment programme also documented improvements in school status, sleep, functional disability, physical mobility, and medication usage after a mean stay of 27 days (Maynard et al., 2010). While these results are encouraging

and point to the possibility of inpatient treatment as a unique and effective treatment choice for children severely disabled by chronic pain, controlled treatment studies of intensive day treatment or inpatient pain rehabilitation remain sorely needed to justify the significant cost of these programmes.

## Conclusion

With the current absence of specific clinical practice guidelines for assessment and treatment of paediatric recurrent abdominal pain, or FGIDs more specifically, the best available approach is one consistent with the widely accepted biopsychosocial model. Emphasis on early identification and treatment of all factors (i.e. biological, psychological, and social) that may be playing a contributory role in pain maintenance will provide the best opportunity for effective intervention and prevention of long-term issues. Additional research in this area—with particular emphasis on using current diagnostic classification systems to define samples, employing rigorous methodologies for execution of clinical trials, and attempting to identify the most powerful or necessary components of multicomponent treatment packages—will be necessary to improve the quality and consistency of care provided to this paediatric pain population.

### Case example

Tyler, an 11-year-old boy, was evaluated for a 2-year history of daily abdominal pain, with associated complaints of nausea, bloating, and early satiety. His clinical history was positive for asthma, seasonal allergies, attention deficit hyperactivity disorder, and significant problems with sleep duration and quality. Tyler was being home-schooled and missed extracurricular/social activities several times per week due to pain. Past medical history included evaluation by a gastroenterologist and a naturopathic practitioner, with extensive laboratory testing plus upper and lower endoscopy. Review of Tyler's previous workup revealed normal lab findings, but increased duodenal eosinophil counts on endoscopic biopsies. He had been tried on multiple medications and followed a restricted diet without significant symptom relief.

Tyler's evaluation and initial treatment took place over a period of approximately 4 months. A few of the components considered pivotal in Tyler's treatment are highlighted here. Tyler was diagnosed with FD using the Rome III criteria. In addition to antihistamines and montelukast, he was prescribed oral cromolyn four times daily to address the identified inflammatory component of his abdominal pain. Tyler also was referred to a certified biofeedback practitioner near his home. He attended BART sessions three times per week initially and practised the skills several times per day at home. Tyler's family utilized a structured plan for graduated school re-entry, starting by attending one consistent class period daily and gradually adding time to his in-school schedule as stamina increased. During this process, Tyler also received instruction from a homebound teacher in the classes he was not yet attending. As specific classes were added to his in-school schedule, support for these classes was dropped from homebound and the amount of homebound instruction was reduced. Accommodations also were put in place that allowed Tyler to take breaks for BART practice and to use the toilet, as needed, during the school day.

Routine in-office follow-up continued on a regular basis to monitor progress, provide behavioural coaching, support continued engagement in treatment components, and modify the plan as needed. After 1 month of treatment, Tyler reported that BART was extremely helpful to him in terms of helping to manage his pain. After 4 months of treatment, Tyler reported having abdominal pain about once per week. His appetite, sleep, energy, and headaches also were improved. Within approximately 8 weeks of beginning graduated school re-entry, Tyler was attending school full time and participating in social activities with his peers.

It is important to convey the fact that Tyler's recovery was not perfectly linear, nor has it ended. Although not yet substantiated in the literature, clinical experience has suggested that eosinophilic inflammation within the gastrointestinal tract is especially sensitive to viral illnesses, seasonal allergies, and stress. Consistent with this, Tyler evidenced temporary symptom flares at predictable times during his treatment. While certainly disappointing for Tyler and his family, these setbacks provide important clues for preventing, or at least managing, flares when they occur. Proper hand washing to reduce transmission of viruses, aggressive treatment of seasonal allergies, and advance planning to reduce stress can be helpful in reducing the odds of a temporary increase in gastrointestinal inflammation and associated symptoms. Identifying and addressing potential triggers for future episodes can be an important part of long-term maintenance for an individual child.

## CHAPTER 30

# Chronic pelvic pain in children and adolescents

Susan L. Sager and Marc R. Laufer

### Summary

Pain due to pelvic pathology in children and adolescents is often described as abdominal pain, and frequently coexists with gastrointestinal symptoms due to neuronal cross talk and visceroviscero or viscerosomatic convergence of sensory afferents. Dysmenorrhea is highly prevalent among adolescents yet is underreported. Like many chronic conditions where repetitive noxious stimuli are present, dysmenorrhea can be associated with central sensitization of pain pathways and visceral hyperalgesia. In this chapter the components of a menstrual history, the importance of obtaining a menstrual history in adolescents with abdominopelvic pain, and the indications for referral to an adolescent gynaecologist are discussed. Endometriosis should be considered in the differential diagnosis of all females with chronic abdominopelvic pain of undetermined aetiology once the benchmark of thelarche has been met. Other overlooked causes of abdominopelvic pain include intercostal or subcostal neuralgias, nerve compression, and abdominal cutaneous nerve entrapment. A multidisciplinary approach to treatment of the patient with chronic abdominopelvic pain is discussed.

### Introduction

Pelvic and abdominal pain is a common complaint in paediatric and adolescent primary care, and in some cases, persists into adulthood (Campo et al., 2001; Walker et al., 1995). Pelvic pain is a broad term that encompasses pain originating from viscera within the pelvic cavity, and from the myofascial and bony structures that comprise the pelvis. Pain due to pelvic pathology can be referred to other viscera, the back, abdominal wall, abdomen, hips, and upper thighs, reflecting a broad visceroviscero and viscerosomatic distribution of the sensory and sympathetic afferent neurons of the lumbosacral plexus (Figure 30.1). For many young patients, the distinction between pelvic and abdominal pain is not well appreciated and descriptions of abdominopelvic pain can be highly variable. Accordingly, it is not uncommon for adolescents to describe pain due to pelvic pathology as 'stomach ache,' and also report symptoms of nausea, gastro-oesophageal reflux, constipation, and bloating in addition to abdominopelvic pain. Not surprisingly, many young adolescents with these non-specific symptoms are evaluated first by gastroenterologists and often have a diagnosis of irritable bowel

syndrome (IBS) or functional gastrointestinal disorder (FGID) prior to identifying other pelvic pathology.

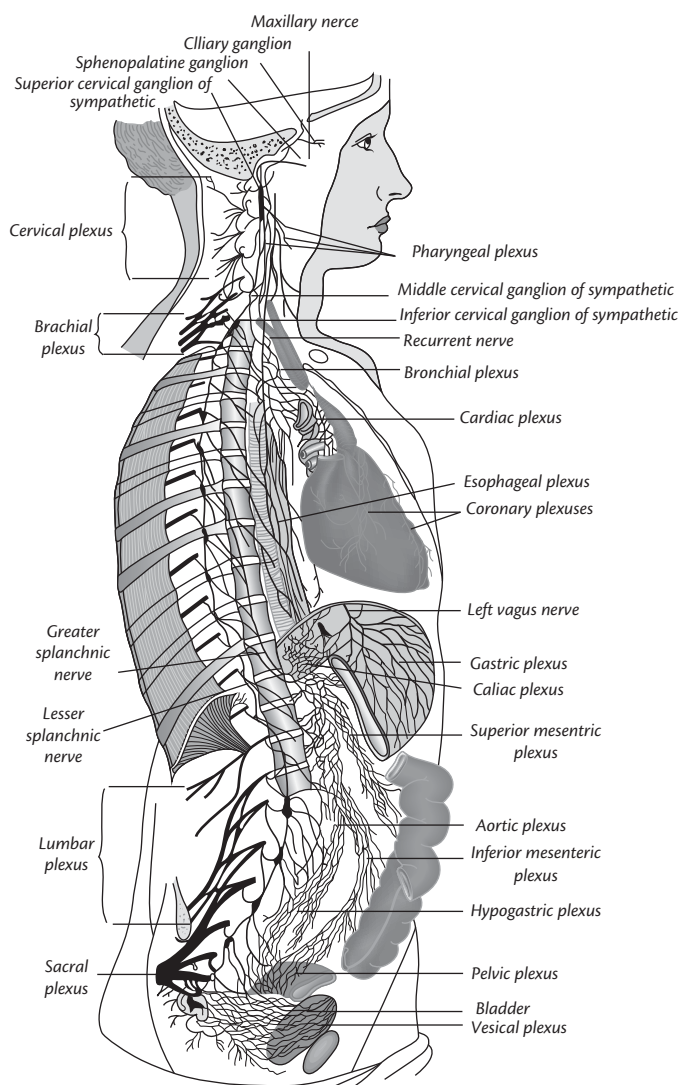

Chronic pelvic pain is associated with changes in the neuronal processing of pain signals in the periphery, dorsal horn, and brain. Pain often persists long after the initiating pelvic inflammation or trauma is resolved. Patients referred for treatment of chronic pelvic pain may have histories that include visceral or musculoskeletal pathology but those initial inciting events have resolved or are being treated effectively by all measures. Further evaluations are often non-revealing of active pathology, and a functional disorder such as IBS becomes the referring diagnosis to the pain specialist. Central sensitization with development of visceral hyperalgesia can provide a framework for understanding why IBS is diagnosed so frequently in patients with pelvic pathology and why patients with pelvic pathology report gastrointestinal symptoms so frequently.

### Causes of chronic pelvic pain

The differential diagnosis of abdominopelvic pain is extensive and includes orthopaedic, gastrointestinal, gynaecological, urological, traumatic, infectious, and neoplastic causes. A careful history will help direct the evaluation. Irritable bowel syndrome and stress are the most common diagnoses received by women with chronic pelvic pain, though many are diagnosed without any investigative tests (Zondervan et al., 2001). The most common causes of chronic pelvic pain in adolescent females are dysmenorrhea and constipation.

### Dysmenorrhea

Dysmenorrhea is a syndrome characterized by recurrent, crampy, lower abdominal pain occurring during menses. Pain is often accompanied by nausea, vomiting, diarrhoea, headaches, and muscular cramps, and frequently co-occurs with other chronic pain conditions, including migraine, IBS, interstitial cystitis, fibromyalgia, and chronic fatigue syndrome (Alagiri et al., 1997). Dysmenorrhea affects up to 90% of post-menarchal adolescents, with 9% to 14% reporting pain as severe (Klein and Litt, 1981), and is the leading reason for missed school days and work in the adolescent population (Schroeder and Sanfilippo, 1999). Yet, under-reporting of symptoms is common and many adolescents do not seek treatment for dysmenorrhea even when symptoms are severe and school days are missed (Klein and Litt, 1981). It is speculated

**Figure 30.1** Anatomy of the nerve supply to the abdomen and pelvis. Reproduced from Henry Gray, *Anatomy of the Human Body*, 1918 edition, Copyright © 1918, with permission from Elsevier.

that many adolescents consider dysmenorrhea a variant of normal, which in part explains underreporting and why epidemiological data on treatment outcomes in young adolescents is lacking. In addition, many adolescents are hesitant to discuss gynaecological issues and have concerns that if they do verbalize their symptoms they may need a bimanual or speculum-assisted pelvic exam.

Dysmenorrhea is a cyclic pain, and recurrent nociceptive input from painful periods each month can lead to neuronal alterations at the level of the spinal cord and brain that persist throughout the menstrual cycle (Vincent et al., 2011). Studies in adults with dysmenorrhea have demonstrated central nervous system changes similar to those seen in other chronic pain conditions. Such changes include altered central processing of noxious stimuli (Vincent et al., 2011), metabolic and morphological changes in the brain as seen on imaging studies (Tu et al., 2009, 2010), alterations in hypothalamic–pituitary–adrenocortical axis function, and reduced quality of life (Vincent et al., 2011). Dysmenorrhea is therefore a cyclic pain that appears to develop features of a chronic neuropathic pain condition over time.

Central nervous system changes associated with dysmenorrhea lead to sensitization of other abdominopelvic viscera and somatic tissues, including bladder, intestine, abdominal wall, and back (Giamberardino et al., 1997). Animal studies have demonstrated that acute inflammation in one pelvic organ (uterus, colon or bladder) will induce inflammatory changes in either nearby or remote organs and affect the function of those organs (Berkley, 2005). This observation has been referred to as a ‘cross-organ affect’ and supports data from other studies demonstrating viscerovisceral convergence of sensory and sympathetic neurons in the spinal cord (Winnard et al., 2006).

Based on a history of pain with menses, the differential is limited. The majority of cases of dysmenorrhea in adolescents are primary, with normal ovulatory cycles and no associated pelvic pathology. Secondary dysmenorrhea refers to painful menstruation associated with pelvic abnormalities, which may be seen in about 10% of adolescents with dysmenorrhea. Referral to a gynaecologist is indicated for evaluation and treatment of severe dysmenorrhea and to rule out the possibility of an obstructive or partially obstructive anomaly such as a transverse vaginal septum, microperforate hymen, or obstructed hemivagina or hemiuterus. When a gynaecological exam is indicated, unlike in adults, the exam is often limited to a cotton swab inserted into the hymenal orifice to help determine if there is an anomaly of the vagina. If there is still concern a transabdominal ultrasound can be helpful.

Dysmenorrhea is typically initially treated with non-steroidal anti-inflammatory drugs (NSAIDs; Marjoribanks et al., 2010). If pain persists then hormonal therapy is used to lighten periods and decrease pain. This is achieved with either combination oestrogen/progestin hormonal pills or progestin-only therapy. Progestin-only therapy is typically utilized if there is a contraindication to the use of oestrogen such as in the case of migraine headaches with focal neurological symptoms or a history of a thrombophilia. If pain resolves with the use of NSAIDs and cyclic hormonal therapy then no further evaluation is usually needed. If pain persists on NSAIDs and hormonal therapy then laparoscopic evaluation is warranted to evaluate for the possibility of endometriosis as the underlying diagnosis. Approximately 70% of adolescents who have a persistence of pain on NSAIDs and 3 months of cyclic hormonal therapy who undergo a laparoscopy have endometriosis (Laufer et al., 1997).

## Endometriosis

Endometriosis is a chronic inflammatory and painful condition defined as the presence of uterine glands and stroma outside the uterus. There is no clear understanding as to how endometriosis causes pain but proposed explanations include prostaglandin production, cytokine production, and adhesion formation. Endometriosis lesions can be found anywhere within the abdominal and pelvic cavity. Most lesions are seen on the ovaries, pelvic walls and cul-de-sac, but can also be found on bowel, bladder, ureters, liver, lung, and scar tissue. There are no laboratory tests or imaging studies diagnostic for endometriosis, and thus adolescent endometriosis is diagnosed by laparoscopic visualization.

In adult women, the most common cause of chronic pelvic pain is endometriosis (Fauconnier and Chapron, 2005), estimated to affect 4% to 17% of post-menarchal females (Ranney, 1980). Population studies of endometriosis in adolescents are likely to underestimate its prevalence due to underreporting of symptoms and failure to diagnose. In adolescents who seek treatment for unexplained

chronic pelvic pain, there is a 47% prevalence rate of endometriosis found at time of laparoscopy (Goldstein et al., 1979). Other studies have shown that 25% to 38% of adolescents with chronic pelvic pain who seek medical care and undergo laparoscopy have endometriosis (Kontoravdis et al., 1999; Vercellini et al., 1989). Empiric treatment with NSAIDs and oral contraceptives (for the treatment of dysmenorrhea as described earlier) can improve symptoms for many adolescents with chronic pelvic pain, but in cases where pain persists, greater than 70% of adolescents with chronic pelvic pain will be diagnosed with endometriosis (Laufer et al., 2003). In a more recent study, 97% of adolescents with persistence of pain on NSAIDs and combination hormonal therapy were found to have endometriosis on laparoscopic evaluation (Opoku-Anane and Laufer, 2012). The increase in prevalence from 70% to 97% may be due to the improvement of optics of laparoscopes with digital imaging.

Although commonly understood to be a disease of adult women, endometriosis can occur in adolescents and in pre-menarchal girls as early as 8 years of age (Marsh and Laufer, 2005). As endometriosis is an oestrogen-dependent disease, endometriosis should be considered in the differential diagnosis of all females with abdominal or pelvic pain once the benchmark of thelarche has been met (Economy and Laufer, 1999; Lubianca et al., 1998). More typically, women are diagnosed during their childbearing years when they seek medical treatment for infertility. However, data from the Endometriosis Association indicate that two-thirds of adult women with endometriosis reported onset of pelvic symptoms during adolescence, with 38% reporting symptom onset before age 15 years (Ballweg, 2004). On average there is a delay of 9 years from onset of symptoms to diagnosis of endometriosis, with longer delays (8–10 years) diagnosing adolescents compared to women in their 30s (<2 years; Ballweg, 2004, Hadfield et al., 1996). Adolescents under age 15 years with chronic pelvic pain saw an average of 4.2 doctors compared with women in their early 30s who saw an average of 2.6 doctors before diagnosis or referral (Ballweg, 2004).

Adolescent endometriosis can be a challenging diagnosis as signs and symptoms are often non-specific for gynaecological pathology and can differ from those reported by adults (Table 30.1). Adult women with endometriosis report gynaecological symptoms of abdominopelvic pain, severe dysmenorrhea, menorrhagia, irregular menses, subfertility or infertility, and acute adnexal pain due to

ovarian cysts more frequently than controls without endometriosis (Ballard et al., 2008). Women experiencing these symptoms have a high risk of having endometriosis, especially if they experience more than one of these symptoms (Ballard et al., 2008). While adolescents may report similar symptoms as adults, 60% of adolescents with endometriosis report either abdominal or pelvic pain, and 90% report pain that occurs during menses (cyclic) as well as pain that is continuous throughout the menstrual cycle (acyclic) (Laufer et al., 1997).

Questioning adolescents about their menstrual history can identify markers associated with endometriosis (Chapron et al., 2011). A positive family history of endometriosis in a first-degree relative (odds ratio (OR) = 3.2; 95% confidence interval (CI): 1.2–8.8) school absenteeism during menstruation (OR = 1.7; 95% CI: 1–3), and use of oral contraceptive pills for treating severe primary dysmenorrhea in girls under 18 years (OR = 4.2; 95% CI: 1.8–10.0) are predictive for endometriosis (Chapron et al., 2011).

Many women with endometriosis report a preponderance of gastrointestinal symptoms and have received a previous diagnosis of IBS or pelvic inflammatory disease (PID) which contributes to the delay in diagnosis of endometriosis in both adults and adolescents. In a consecutive series of 355 women undergoing laparoscopy for suspected endometriosis, 90% of the women with histologically confirmed endometriosis had gastrointestinal symptoms (bloating constipation, diarrhoea, nausea, vomiting). While bloating was the most frequent gastrointestinal symptom, reported by 83% of women, 71% also had other gastrointestinal symptoms (Maroun et al., 2009). Gastrointestinal symptoms are reported nearly as frequently as gynaecological symptoms in women with endometriosis (Maroun et al., 2009). Similarly, a national case-control survey from the UK concluded that 45% of women with endometriosis had a record of abdominal pain and only 15% had a record of pelvic pain (Ballard et al., 2008). Results from the same study also showed that women with endometriosis were 3.5 times more likely to have received a diagnosis of IBS and six times more likely to receive a diagnosis of PID than women without endometriosis (Seaman et al., 2008). There is no data specific for adolescents. The association between endometriosis and PID or IBS was less strong after the diagnosis of endometriosis was made, and these authors suggest some misdiagnosis among women with endometriosis, while posing the possibility of comorbidity between endometriosis and PID or IBS. Whether IBS coexists with endometriosis or is secondary to development of visceral hyperalgesia due to this chronic inflammatory disease is not known. Accordingly, endometriosis should be considered in the differential diagnosis of all females with abdominal or pelvic pain when a functional gastrointestinal disorder such as IBS is considered once the benchmark of thelarche has been met (Economy and Laufer, 1999).

Laparoscopic findings in adolescents also differ from adults, and a prior ‘negative’ laparoscopy should not rule out the possibility of endometriosis if a surgeon or gynaecologist unfamiliar with the appearance of adolescent endometriosis lesions performed the procedure. Under direct vision, endometriosis lesions in adolescents typically appear as red and clear lesions and the more classic black or brown lesions are more commonly seen in adult women (Laufer et al., 2003). The clear lesions can be difficult to visualize without the use of specialized surgical techniques. Endometriomas, a collection of endometriosis in the ovary, also commonly referred to as a ‘chocolate cyst’ are rarely seen in adolescents but have been

**Table 30.1** Symptoms of adolescents with endometriosis

Vaginal discharge	6.3

Source: data from Laufer, M. et al., Prevalence of endometriosis in adolescent girls with chronic pelvic pain not responding to conventional therapy, *Journal of Pediatric and Adolescent Gynecology*, Volume 10, Issue 4, pp. 199–202, Copyright © 1997 North American Society for Pediatric and Adolescent Gynecology. Published by Elsevier Inc. All rights reserved.

reported (Wright and Laufer, 2010). A high index of suspicion and knowledge of the differences in presentation between adult women and adolescents is key to identifying and treating endometriosis. There is lack of long-term data on follow-up of endometriosis treatment. One long-term follow-up study shows that with early diagnosis and treatment, disease progression may be retarded (Doyle et al., 2009).

The pathogenesis of endometriosis remains unclear. Several theories have attempted to explain possible aetiologies, including developmental anomalies, retrograde menstruation, failure of endometrial cell apoptosis, immune and inflammatory disease, and genetics (Bulun, 2009). There is a 6.9% increased risk of endometriosis of first-degree relatives with endometriosis (Simpson et al., 1980). Other research suggests endometriosis, like migraine headache, is a neurovascular disease (Zhang et al., 2008), and indeed, compared to women without endometriosis, women with endometriosis have an increased density of sensory nerve fibres in the peritoneum and eutopic endometrium (Berkley et al., 2005; Tokushige et al., 2006).

Visceral hyperalgesia is a common finding in patients with endometriosis (Issa et al., 2012). The role of chronic inflammation in the development of visceral hyperalgesia and neuropathic pain was the subject of a recent review of endometriosis pain mechanisms (Evans et al., 2007). The authors identified research showing invasion of nociceptors into peritoneal endometriosis lesions and increased number of nerve terminals in endometriotic tissue, as well as activation of nociceptors by inflammatory mediators, sprouting of new nociceptors, and activation of silent nociceptors present in normal endometrium and peritoneum (Anaf et al., 2006; Berkley et al., 2005; Tokushige et al., 2006). The authors speculate that such nerve sprouting might be caused by increased levels of nerve growth factor (NGF), since expression of NGF in endometriotic tissue is reported to be higher than in eutopic endometrium (Anaf et al., 2006; Tokushige et al., 2006).

Increased signalling from visceral nociceptors to the spinal cord leads to sensitization of dorsal horn cells, convergence of visceral and somatic afferent pathways, and alterations in neural modulation of inhibitory and excitatory pain pathways throughout the central nervous system due to neuroplasticity (Bajaj et al., 2003; Berkley, 2005). Over time, pain spreads to other viscera (viscero-visceral hyperalgesia) and to the abdominal wall and back (viscero-somatic hyperalgesia) with somatic symptoms of cutaneous hypersensitivity to touch, i.e. allodynia (Giamberardino et al., 2010).

Currently there is no cure for endometriosis and treatment is aimed at controlling progression of disease and pain relief. Guidelines from the American College of Obstetricians and Gynecologists (ACOG) for management of adolescent endometriosis pain are extrapolated from the adult experience with endometriosis pain. Recommendations include surgical destruction and/or removal of visible lesions, hormonal suppression of ovulation and menstruation, and anti-inflammatory analgesics (ACOG, 2005). Surgical destruction of endometriosis and menstrual suppressive therapy can retard disease progression (Doyle et al., 2009). Yet, these interventions are variably effective and many adolescents continue to report pain despite anti-endometriosis therapy. Managing chronic pelvic pain due to endometriosis is a multidisciplinary endeavour and communication among clinicians across disciplines, including pain medicine, gynaecology, and psychology, is essential for good pain treatment outcomes.

Acute exacerbations in endometriosis pain may be surgical or non-surgical and an effort should be made to identify the cause of an acute increase in pain. Non-surgical causes of acute pain flares include a missed or delayed oral contraceptive pill, change in absorption of oral contraceptives due to medications, or change-over in hormonal therapy. Suspected ovarian torsion, tubal, or ovarian cysts, and adhesions require surgical evaluation. Close communication with the patient's gynaecologist is important to understanding the aetiology of episodic pain flares, and informs pain management.

### Pelvic floor dysfunction

Pelvic floor dysfunction is being recognized more frequently as a cause of chronic pelvic pain in children and adolescents. In adults, pelvic floor dysfunction is associated increasing age and parity, and structural or mechanical changes in the pelvis (Baessler et al., 2004; Kepenekci et al., 2011; MacLellan et al., 2000). Injury to the sacrum, coccyx, pubis, and hip joints can be a cause of misalignment, tension, and inflammation of the attached ligaments, muscles, and nerves in the pelvis. Pain syndromes associated with pelvic floor dysfunction include interstitial cystitis/painful bladder syndrome (IC/PBS), chronic prostatitis/painful prostate syndrome (CP/PPS), vulvodynia, proctalgia fugax, coccyxdynia, piriformis syndrome, pudendal nerve entrapment, and others.

In children, pelvic floor tension myalgia is associated with voiding or elimination dysfunction, and spasm of the pelvic floor muscles. The typical presentation in children is night time awakening with severe lower abdominal or perineal pain. Urodynamic studies often identify high urethral pressures without structural obstruction of the outflow tract (Hoebeke et al., 2004). Conditions associated with pelvic floor dysfunction have been shown to respond well to biofeedback-assisted pelvic floor relaxation therapy (Li et al., 2006).

### Chronic prostatitis/prostatic pain syndrome

In adolescent males, CP/PPS is defined by symptoms of voiding dysfunction (frequency, urgency, split stream and sense of residual urine) and pain (testicular, penile, scrotal, pelvic or rectal) as well as ejaculatory pain or discomfort. Males rarely exhibit these symptoms before puberty (Hoebeke et al., 2004; Tripp et al., 2009). However, in a study of North American adolescent males aged 16 to 19 years, the prevalence of CP was found to be 8.3%, comparable to adults (Tripp et al., 2009). Unlike adult CP, adolescents reported a preponderance of voiding symptoms, which led authors to conclude that CP in adolescents is most likely due to pelvic floor dysfunction (Li et al., 2006).

### Interstitial cystitis/bladder pain syndrome

IC/PBS is a condition frequently occurring with endometriosis and IBS, and can be a related cause of chronic pelvic pain. Characteristic symptoms of IC include urinary frequency and urgency, usually with pelvic pain and nocturia, in the absence of bacterial infection or any other identifiable pathology. In adults, it is estimated that 85% of patients with chronic pelvic pain may have symptoms of IC (Parsons and Albo, 2002). The incidence of IC in children and adolescents is not known. In adults, IC is being identified more frequently with the use of the Interstitial Cystitis Symptom Index, a symptoms questionnaire (Clemons et al., 2002), and an intravesical

potassium sensitivity test (PST; Chung et al., 2010). The PST is an office-based test useful for isolating the bladder as the source of pain and urgency symptoms. Potassium instilled into the bladder is a neuroirritant and causes an increase in pain symptoms. A positive PST suggests increased permeability of the bladder urothelium and lends support to the diagnosis of IC. Alternatively, instilling anaesthetic solution may also aid in the diagnosis of IC. The diagnosis is confirmed by cystoscopy. If IC is detected, then the patient can be treated for chronic pelvic pain of bladder origin. Urological therapy for IC has a high rate of success and often is best treated in a multidisciplinary setting.

## Assessment

A careful history can help direct the workup and evaluation of patients with chronic pelvic pain. Quality and location of pain can help determine whether pain symptoms originate from viscera, are musculoskeletal, or from an entrapped nerve. Pain descriptors such as burning, aching, stabbing, spreading, or throbbing are common in patients with visceral hyperalgesia or neuralgia; inability to tolerate any tight fitting clothing and hypersensitivity of the abdominal wall or back to light touch or gentle pressure can indicate viscerosomatic convergence with referred pain to the abdomen or back. In addition to asking about location, onset, and frequency of pain symptoms, questioning for temporal association with injury or trauma such as an occult pelvic fracture, or suspected slipped capital femoral epiphysis, hip, or back injury can identify treatable orthopaedic conditions. Gastrointestinal and urinary symptoms often coexist with other pelvic pathology.

Obtaining a menstrual history and understanding norms for menstrual frequency, amount of bleeding, and severity of pain is important in order to determine whether further gynaecological investigation is needed when evaluating a patient referred for chronic abdominopelvic pain. For example, irregular periods are considered the norm for young teens because of anovulation; however, it is not well appreciated that during the early years after menarche, 90% of cycles will be within the range of 20 to 45 days even during the first gynaecological year (Popat et al., 2008). Cycles outside of the range of 20 to 45 days are statistically uncommon, even in young girls, and deserve evaluation for potential treatable causes.

A medication history may reveal that the patient is on an oral contraceptive pill. It is important to determine whether the pill was started for menstrual irregularities or pain, and note whether symptoms have improved since starting hormonal therapy. A family history of gynaecological disorders such as endometriosis, severe dysmenorrhea, or infertility can guide referral to an adolescent gynaecologist. A patient with a positive family history of endometriosis in a first-degree relative has a 6.9% increased risk of endometriosis in comparison with a 1% risk in controls (Simpson et al., 1980).

During the interview or exam, time should be set aside to speak confidentially with the patient about sexual activity, history of physical or sexual assault, and sexually transmitted infections as information on these sensitive subjects may be withheld in the presence of parents or guardians. In a systematic review of risk factors in women with and without chronic pelvic pain, Lathe et al identified a strong association between all types of chronic pelvic pain and pelvic pathology, history of childhood abuse, and psychological morbidity in adults (Lathe et al., 2006).

On physical exam, evaluation of the spine and pelvis looking for posture, gait, symmetry, range of motion, and tenderness to palpation may reveal biomechanical alterations. Leg-length discrepancy and pathology of the spine or hip can be referred to the groin and pelvis. A sensory exam of the back and abdomen to determine the presence of allodynia or hyperalgesia can provide evidence of central sensitization and neuropathic pain. Pain of visceral origin and associated viscerosomatic convergence may present as a non-dermatomal area of hyperalgesia or allodynia over the abdomen or back.

A dermatomal distribution of pain over the abdomen is suggestive of an intercostal or subcostal neuralgia, and may indicate pathology at any point along the nerve as it exits the spinal canal. Palpation of the area may reveal proximal and distal radiation along the course of the nerve, known as Valleix phenomenon. Neuroimaging of the spine is indicated if more proximal nerve involvement is suspected. Less commonly, tumour or herpes zoster is the cause.

Abdominal cutaneous nerve entrapment syndrome (ACNES) or an intercostal neuralgia can be overlooked causes of chronic abdominopelvic pain. The abdominal wall is innervated by the anterior rami of the lower six thoracic nerves (T7–T12) and the first lumbar nerve (L1–L2). Thoraco-abdominal nerves exit the spinal canal and terminate in posterior, lateral and anterior branches, providing sensory innervation to the abdominal wall and overlying skin. Similarly, L1 to L2 subcostal nerve involvement (ilioinguinal/iliohypogastric nerves) may present as vulvar or groin pain in girls or scrotal pain in boys. Terminal branches of these somatic nerves course through the lateral abdominal wall within a plane between the internal oblique and transversus abdominis muscles. The thoracic branches are anchored at various points through fibrous attachments within the wall which can tether or trap the nerve along its course as it passes to the superficial layers. The anterior cutaneous branch of an intercostal nerve is most vulnerable to entrapment because it makes a nearly 90-degree turn to enter a fibrous tunnel as it passes to the superficial tissues at the lateral border of the rectus abdominis muscle. A history of straining, coughing, or vomiting may be elicited as increased intra-abdominal pressure, intense muscle contraction, or blunt trauma to the abdominal wall can lead to nerve entrapment. Postoperatively, traction can be placed on the nerve by a scar.

On exam, one can look for a positive Carnett's sign. With the patient in the supine position, the examiner palpates along the lateral border of the rectus sheath and asks the patient to attempt a sit up. As the patient tenses the abdominal wall muscles, if entrapped, the anterior branch of the intercostal nerve becomes compressed between the examiner's finger and the taught abdominal muscles, resulting in worsening pain. If pain is from the viscera, tensing the muscles guards against more painful deeper palpation. Abdominal wall pain can be distinguished from visceral pain with a transversus abdominis plane (TAP) block, which numbs the abdominal wall. A rectus sheath block may relieve an abdominal cutaneous nerve entrapment; abdominal wall trigger points may have a similar presentation and can be identified with careful palpation.

## General approach to treatment (Table 30.2)

When acute inflammatory pain is suspected, NSAIDs and opioid analgesics can provide good pain relief. It is known that non-steroidal anti-inflammatory analgesics are not as effective for treating neuropathic pain and visceral hyperalgesia (Cruccu et al., 2007;

**Table 30.2** Approach to multidisciplinary treatment of pelvic pain in adolescents

Medications	NSAIDS
	Anticonvulsant
	Tricyclic antidepressants
	Tramadol/oxycodone
Nerve blocks	Lidoderm patch
	Trigger point injections
	Transversus abdominis plane (TAP)
	Pudendal nerve
Physical therapy	Ganglion impar
	Aquatherapy
	Pelvic floor retraining
	Core strengthening
	Endurance
	Flexibility
Biobehavioural therapies	TENS unit
	Cognitive behavioural therapy
	Biofeedback
	Guided imagery
	Treatment of depression and anxiety
Complementary and alternative therapies	Assistance with school reentry
	Acupuncture
	Acupressure
	Therapeutic massage

Dworkin et al., 2007). Development of central sensitization and chronic neuropathic pain may explain why pain continues despite treatment with standard anti-endometriosis therapies.

Neuropathic pain analgesics include tricyclic antidepressants and anticonvulsants. First-line agents most commonly used for treatment of neuropathic pain conditions include amitriptyline and gabapentin, typically chosen based on side effect profile as there is yet no data to support one class of drug over the other as far as pain relief efficacy. There is no data on the use of these drugs in patients with endometriosis.

Complicating the treatment of chronic pelvic pain is the observation that many adolescents with endometriosis and persistent pain have symptoms of anxiety and/or depression. Psychological support to develop pain coping strategies and to treat associated symptoms of depression or anxiety is part of a multidisciplinary approach to pain management. When medication is initiated, the selective serotonin re-uptake inhibitor class of antidepressants is frequently prescribed for depression and/or anxiety. When medication for anxiety or depression is a consideration, therapeutic dosing of amitriptyline as a neuropathic analgesic in the treatment of endometriosis pain can be limited due to concern for increased risk of serotonin syndrome. Additionally, many adolescents are concerned about weight gain, and have a history of IBS with constipation, both of which can be exacerbated by a tricyclic antidepressant and ultimately lead to medication non-compliance.

Patients benefit from physical therapy as part of a multidisciplinary approach to treatment of chronic pelvic pain. Prolonged periods of bed rest and compensatory postures can lead to myofascial pain and deconditioning, adding to the overall level of pain-related disability. When the patient has become homebound and no longer participates in athletic or after school activities the rationale for functional restoration is evident. Aquatherapy, gentle stretching, core and pelvic floor strengthening, and building endurance in a therapeutic setting can be the first steps toward re-engaging the patient in everyday activities.

Referred pain from the viscera, and visceros-somatic convergence of neural sensory pathways at the level of the spinal cord can result in allodynia and hyperalgesia of the abdominal wall. Transcutaneous electrical nerve stimulation (TENS) or topical application of a 5% lidocaine patch (Lidoderm®) can provide additional pain relief when the abdominal wall or back are tender. TENS involves stimulation of the skin using electrical currents at various pulse rates (frequencies) and intensities in order to provide pain relief. A conventional TENS emits pulses between 50 and 120 Hz at a low intensity producing a tapping or gentle buzzing sensation. It is speculated that TENS relieves pain by stimulating myelinated afferents, which in turn activate segmental inhibitory pathways, thereby altering the body's ability to receive or perceive pain signals. TENS units are the size of a small pager with attached electrodes that adhere to the skin at the site of pain. The units can be worn throughout the day, with the patient controlling the level of current for maximal comfort. Typically, physical therapists will trial a TENS unit over the abdomen and make recommendations for obtaining a unit for home use. The available data on high-frequency TENS suggest it is effective for the treatment of dysmenorrhea (Proctor et al., 2002; Walsh et al., 2009).

The use of acupuncture in managing painful periods is promising though data is limited. Findings should be interpreted with caution due to the small number of studies and study participants. No significant adverse effects were identified in this review (Smith et al., 2011).

When indicated, abdominal wall trigger point injections and TAP blocks can provide temporary pain relief, and help establish a diagnosis of abdominal wall neuralgia, a consideration when treating patients with abdominal incisions/scars, abdominal wall adhesions, or when nerve entrapment is suspected. Pain that is localized to the perineum may respond to a pudendal nerve or ganglion impar block.

## Conclusions

Chronic pelvic pain is often described as abdominal pain in younger patients. Dysmenorrhea is more common in adolescents than adults and can be associated with changes in the central nervous system and other chronic pain conditions due to neuroplasticity. Central sensitization of visceral pain pathways can affect bowel and bladder function, and be associated with pelvic floor pain and dysfunction, which may be improved with physical therapy. In female adolescents with chronic abdominopelvic pain of undetermined aetiology, it is important to have a high index of suspicion for endometriosis, especially when a prior diagnosis of IBS is present. The diagnosis of endometriosis is commonly delayed until adulthood though symptoms start during adolescence. Adolescents with endometriosis can report either cyclic or acyclic pain and present with a preponderance of gastrointestinal symptoms. Obtaining a full menstrual history is an important aspect of the evaluation of female adolescents with chronic abdominopelvic pain.

### Case example

A 14-year-old-female who has been to the emergency department (ED) many times over the past year for recurrent flare-ups of abdominal pain has received intravenous analgesia with ketorolac and morphine with transient relief. She has been thoroughly investigated for abdominal pain by multiple specialists from gastroenterology and general surgery over the preceding year. These investigations included computed tomography scans, abdominal and pelvic ultrasounds, HIDA (hepatobiliary iminodiacetic acid) scan and gall bladder emptying studies, and blood tests to rule out coeliac disease, infectious, and IBDs. Last year she underwent laparoscopic cholecystectomy for presumed gallbladder dysfunction, and at the same time had her appendix removed pre-emptively. The procedure was uneventful but she continued to report severe pain postoperatively. Repeated upper and lower endoscopies did not reveal abnormalities. She is being treated for IBS and gastro-oesophageal reflux disorder. At the time of her most recent ED visit, she presented with periumbilical and left lower quadrant pain which did not respond to repeated doses of intravenous morphine. The decision was made to admit the patient to the hospital for further evaluation of chronic abdominal pain and pain management.

Additional history revealed that her paediatrician has suggested she meet with a psychologist because of depressed mood and school avoidance. The patient started high school this year and has missed many days of school due to pain. She has stopped playing soccer and cheerleading due to pain, activities she previously enjoyed. She has withdrawn from peers and social activities. The patient spends most her time at home resting on the couch and worrying about undiagnosed serious illness. She feels that some healthcare providers no longer believe she has pain and view her as 'faking.' Sleep is difficult to initiate and non-restorative. She will probably have to repeat ninth grade due to absences.

The patient describes periumbilical and left lower quadrant pain that is present all the time to a variable degree. The pain symptoms developed gradually over the past 18 months. She cannot recall an inciting event or illness. The pain is described as a sharp, stabbing, and sometimes throbbing sensation that comes on randomly without obvious triggers. Any tight-fitting clothing over her abdomen worsens the pain. The pain is always present, but can range in intensity from 5 to 10/10 on a numerical rating scale. The pain is not related to food intake, bowel movements, or voiding, though sometimes these activities cause pain to increase. Pain is sometimes worse with menses but can occur any time of the month. She has occasional nausea but has not vomited. Bowel and bladder patterns have not changed. She has a history of constipation and is treated with Miralax®. She has an upcoming appointment with the Pain Treatment Clinic for evaluation of new low back pain.

Past medical history is significant for menarche at age 11 years. Menses are irregular and she takes an oral contraceptive pill. She is followed by GI for IBS, diagnosed at age 12 years with associated GERD which is treated with Prevacid® and constipation, treated with Miralax®. Previous surgeries include laparoscopic cholecystectomy and appendectomy. Family history reveals that her mother and aunts had difficulty conceiving.

On physical exam she is very anxious, lying on her right side, and crying. Vital signs: heart rate 93/min, regular; respiratory rate 15/min, crying; blood pressure 115/65; room air SpO<sub>2</sub> = 100%.

General physical and brief neurological examination revealed no abnormalities except for her abdominal examination: her abdomen was soft, non-distended, with decreased bowel sounds. Laparoscopic port sites located in the umbilicus, midline below the umbilicus, and left lower quadrant were well healed. The abdominal tenderness was diffuse, but greatest over the left lower quadrant and periumbilical area. Light touch or superficial palpation caused pain and she was unable to tolerate deep palpation. Carnett's test was negative. Abdominal examination otherwise was unremarkable.

Differential diagnosis:

- ♦ Visceral hyperalgesia due to central sensitization.
- ♦ Viscero-somatic convergence and referred pain from viscera.
- ♦ Abdominal cutaneous nerve entrapment (ACNE).
- ♦ Intercostal (T7–T12) or subcostal (L1) neuralgia.

Further history revealed that the patient had started taking oral contraceptives for irregular menses at the age of 13 years. She slept over a friend's house and forgot to take her pill the day before her pain developed. Her mother had a history of heavy and painful periods and both of her maternal aunts were diagnosed with endometriosis when they underwent laparoscopy as part of an infertility workup.

This patient was referred to an adolescent gynaecologist for evaluation. With her history of persistent abdominopelvic pain while on an oral contraceptive and positive family history of endometriosis, this patient has a high chance of being diagnosed with endometriosis.

At the time of laparoscopy she was found to have stage I endometriosis. The surgeon proceeded to cauterize visible lesions in the abdomen and pelvis. She was treated with a continuous oral contraceptive (without breaks or placebos for suppression of menses), and was started on gabapentin for treatment of the neuropathic component of her pain symptoms. Over the next 2 to 3 months, she had several episodes of painful spotting. Her pain symptoms flared and did not respond to NSAIDs. Her gynaecologist made some changes to her hormonal therapy to improve suppression of ovulation. She received a prescription for tramadol 25 to 50 mg every 8 h, with instructions to take no more than 3 to 5 days during the month.

Subsequently, with the combination of hormonal suppression, NSAIDs, gabapentin, and occasional tramadol, her pain symptoms subsided. She was able to return to school and began to work with a psychologist, and started taking an antidepressant for her mood symptoms. One month after her surgery, the patient was able to return to school for two classes a day, and within 2 weeks she was attending school full time, participating in gym class, and playing softball with her freshman team. She still has occasional severe cramping, but her pain is manageable on her current regimen and does not interfere with her desired activities.

# CHAPTER 31

## Headaches

Andrew D. Hershey

### Introduction

A complaint of headache is one of the most common health complaints in children and adolescents with migraine representing one of the most common diseases of childhood. However, a complaint of headache is frequently ignored as a problem by patients, parents, teachers, and practitioners. Headaches are either due to an inciting event or illness (secondary headache) or can be a disease by itself (primary headache). Secondary headaches are due to an event or illness and can be recognized by their cause and effect association with this specific aetiology. Once the inciting event is treated or resolves, the headache should also resolve. When the headache persists, additional evaluation is needed. This cause and effect relationship can be confusing in patients with a primary headache. Oftentimes patients with primary headaches make an assumption that their headache is caused by other frequent problems in childhood including mild head injury, infections, and allergies. Furthermore, some of the secondary causes can exacerbate primary headaches in those patients prone to headaches. Lack of headache response to treatment of this presumed secondary cause, or recurrence of the headache without the associated secondary cause, is an indication that the incorrect secondary cause was identified, the incorrect treatment was chosen, or most likely that a primary headache was the actual aetiology.

Recurrent headaches, especially when episodic, are much more likely to represent primary headache disorders. Primary headaches are intrinsic to the nervous system and are the disease itself. Early recognition of the primary headaches in patients should result in improved response and outcome, minimizing the impact of the primary headaches and disability. Primary headaches can be grouped into migraine, tension-type headaches (TTHs), and trigeminal autonomic cephalalgia, and an additional grouping of rarer headaches without a secondary cause. The primary headache that has the greatest impact on a child's quality of life and disability is migraine and subsequently is the most frequent primary headache brought to the attention of parents, primary care providers, and school nurses (Figure 31.1).

### Primary headaches

#### Migraine

Recurrent paediatric migraine has the most significant impact on a child's and parents' lives and consequentially will have the greatest potential improvement with optimal care. There remain many gaps in the recognition and management of migraine during childhood

and often extrapolation from studies in adult headaches are incomplete or inaccurate when translated to children. Future studies should help to fill in the current gaps to further improve the lives of these children and their families.

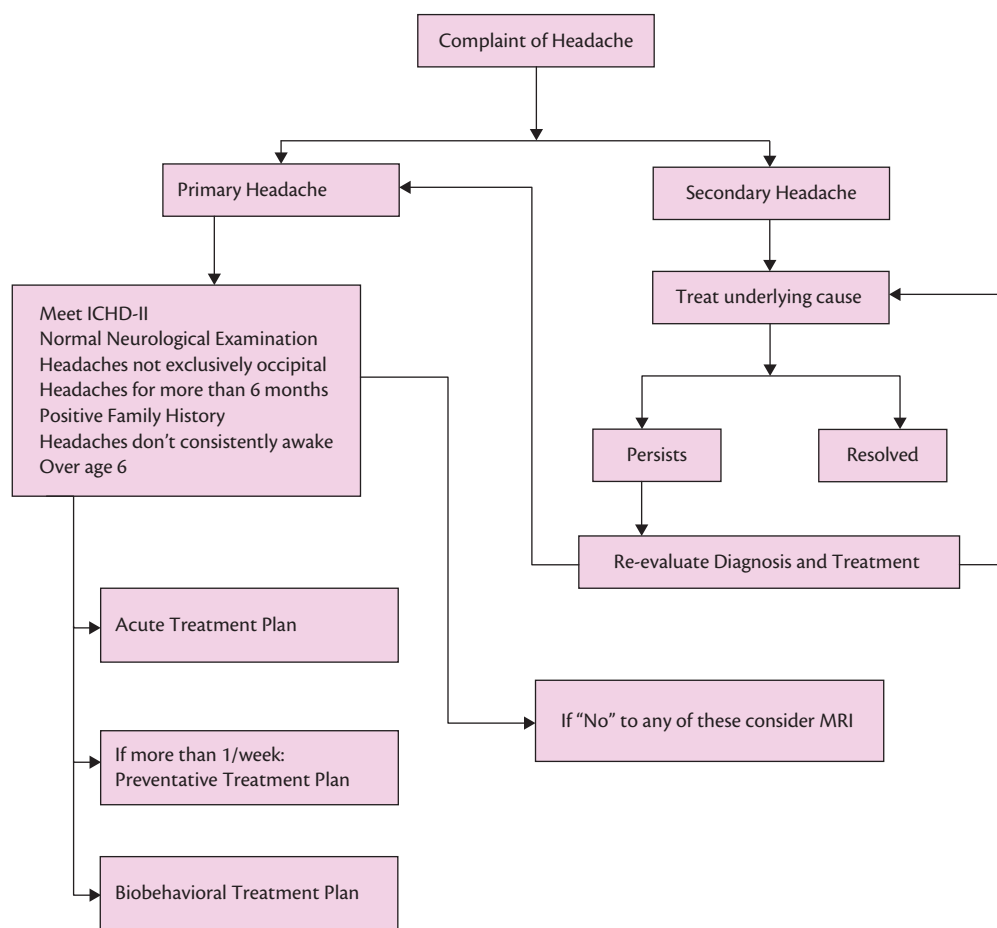

#### Epidemiology

Bille reported the first extensive study of paediatric migraine's epidemiology in 1962 (Bille, 1962). This study used its own criteria for the definition of migraine in children that are no longer used. Even given that limitation, the study established the basis of paediatric migraine epidemiology recognizing that by age 15 nearly 75% of children will report having a significant headache with migraine in 3.9% of children age 7 to 15 years.

Epidemiology studies that have followed confirmed the high frequency of headaches in children and adolescents with migraines being the more disabling problem (reviewed by Winner and Hershey, 2007). The current standard for diagnosis used in scientific studies of headaches is the International Classification of Headache Disorders, second edition (ICHD-II; Headache Classification Subcommittee of the International Headache Society, 2004). These criteria have been widely utilized across a variety of countries with some degree of variation but consistently demonstrate the high prevalence of migraine during childhood.

Epidemiology studies have demonstrated a high frequency of self-reported headache with migraine occurring typically in one out of ten children. A study from Istanbul, Turkey found 46.2% of children age 5 to 13 years old (mean  $8.2 \pm 2.4$  years) reported a significant headache with 3.4% having migraine and an additional 8.7% having probable migraine (Isik et al., 2009). Another study from Turkey compared the prevalence of migraine and TTH using ICHD-II criteria and found migraine to be more common than TTH (21.3% versus 5.1%) with a further increase in the prevalence if the ICHD-II criteria of number of headaches and duration of the headaches were excluded (29.9% and 15.0%, respectively; Unalp et al., 2007). All headache types were found to be more common in females, with an increase in TTH in subjects with a temple location of their pain, having more than one sibling, and parent's education above high school. School absenteeism was higher in the migraine subjects.

Epidemiology studies of the transition from late adolescent to young adult years are rare. One relatively older study that focused on 15- to 19-year-olds found up to 28% of this age group had migraine with 19% having only migraine without aura and 9% having migraine with aura (Split and Neuman, 1999). There was an

**Figure 31.1** Schematic of diagnosis of evaluation of a child presenting with a complaint of headache.

increasing prevalence from age 15 to 19 with a female predominance for all ages. As this appears to be an area of growing prevalence, additional studies are needed to characterize these trends.

### Pathophysiology

The pathophysiology of migraine in children and adolescents is likely the same as in adults, although the differences in headache characteristics in children need to be further investigated. The pathophysiology of migraine can be divided into the underlying biological risk factors for the expression of migraine and the specific biological processes that occur during the attack.

The predominant risk factor for the development of migraine is the inheritance of the genetic potential with the environmental influences contributing to the phenotypic expression of this genotype (Hershey, 2007; van de Ven et al., 2009; Wessman et al., 2007). Several models have demonstrated a genetic aetiology with shared environmental influence and the non-shared environmental influences. The best fitting model demonstrated a genetic influence of 60% to 70% with a non-shared environmental influence composing the remainder. This model suggests that migraine is a genetic disease, but with environmental factors significantly contributing to its expression.

The contribution of individual genes has begun to be identified. The identification of genes directly responsible for familial hemiplegic migraine—*CACNA1A* (Ophoff et al., 1996; Terwindt et al., 1998), *ATP1A2* (De Fusco et al., 2003; Vanmolkot et al., 2003),

and *SCN1A* (Dichgans et al., 2005), has provided insight into the importance of channels and astrocytes in migraine.

Several other biological processes have been identified to be altered or associated with migraine in children and adults including immunological changes (Bockowski et al., 2009), increased levels of calcitonin gene-related peptide in migraine patients (Fan et al., 2009), decreased levels of coenzyme Q<sub>10</sub> (Hershey et al., 2007), and hormonal changes (Crawford et al., 2009; Kroner-Herwig and Vath, 2009; Martin and Behbehani, 2006a, 2006b).

There also appears to be neurophysiological changes. In adult patients it has been found that interictally, patients with migraine have trigeminal sensitization as revealed by an altered blink reflex (De Marinis et al., 2003; Katsarava et al., 2002, 2003; Kaube et al., 2002), auditory response (Siniatchkin et al., 2003; W. Wang and Schoenen, 1998), and sensitization of the trigeminal vascular system (Burstein et al., 2005). In children, several studies have also identified similar neurophysiological and biological changes including alterations in the P100 visual response during visual-evoked potential testing (Unay et al., 2008), changes in the somatosensory-evoked potential with treatment of paediatric migraine (Vollono et al., 2010), habituation mismatch negativity and the P300 response (Valeriani et al., 2009), and impaired auditory response during an acute migraine using magnetic encephalography (Korostenskaja et al., 2011). In sum, these studies clearly demonstrate that during an acute migraine, there is brain dysfunction at the cellular and electrical level.

Cutaneous allodynia due to central sensitization has been studied as a clinical marker that reflects these neurophysiological changes in adults (Ashkenazi et al., 2007; Bigal et al., 2008; Burstein and Cutrer, 2000; Burstein et al., 2000; Jakubowski et al., 2005; Mathew et al., 2004). In subjects that have these symptoms during their migraine, there may be diminished response to treatment (Burstein and Jakubowski, 2004; Burstein et al., 2004; Jakubowski et al., 2005) and possible disease progression. In children this has only begun to be examined with limited findings (Eidlitz-Markus et al., 2007).

### Diagnosis and evaluation

The International Headache Society has established diagnostic criteria for all headache subtypes including primary and secondary headaches—the ICHD-II (Headache Classification Subcommittee of the International Headache Society, 2004). These criteria have been widely used for both the clinical characterization of headaches and as a foundation for research in headaches. One of the keys to these criteria is the separation of those headaches thought to be intrinsic to the nervous system (primary headaches) and those headaches directly attributable to another cause (secondary headaches) with the first step in evaluation of recurrent headaches to eliminate the potential of a secondary headache. If a secondary aetiology is suspected, this should be initially evaluated and treated. If the suspected secondary aetiology is successfully treated, but the headache persists, diagnosis should be re-evaluated.

After the potential of secondary headache has been eliminated, a diagnosis of a primary headache can be made. The ICHD-II has three main categories of primary headaches and a fourth category for those rare headaches that are primary, but don't fall into one of these three main categories: migraine, TTHs, and trigeminal autonomic cephalalgias (including cluster headaches). In children, the most common types of primary headache are migraine and TTH.

Migraine can be subdivided into migraine without aura and migraine with aura, as well as additional migraine-related diagnoses including childhood periodic syndromes, retinal migraine, migraine complications, and probable migraine.

The ICHD-II criteria for migraine without aura and migraine with aura are undergoing revisions, but few changes are expected. For a migraine without aura the keys in the diagnosis include a recurrent headache disorder (at least five attacks) lasting 4 to 72 h, characterized by a focal, throbbing pain, that alters or worsens with activity and is of moderate to severe in intensity (two of four characteristics required) and associated with either nausea and/or vomiting or with photophobia and phonophobia (Headache Classification Subcommittee of the International Headache Society, 2004).

The ICHD-II addressed some of the unique issues related to childhood headaches resulting in an improvement in the specificity and sensitivity, although gaps do remain (Hershey et al., 2005; Lima et al., 2005; Rossi et al., 2008; Ruangsuwan and Sriudomkajorn, 2007): that childhood migraine tends to be of shorter duration (down to 1 h), that sleep should be included as part of the duration, that the location is more likely bilateral (typically frontal temporal), and that photophobia and phonophobia could be inferred by the parents and care providers based on the child's actions. The ICHD-II noted that if the location is exclusively occipital then additional workup is warranted.

Although the criteria do not completely recognize all children with migraine, these criteria should be used as a guideline for making the diagnosis. Use of standardized questionnaires with a

semistructured interview can assist with assuring the completeness of this evaluation (Hershey et al., 1999). Such an approach has been shown to be very sensitive and specific in making the appropriate diagnosis of headache (Valentinis et al., 2009). This evaluation must incorporate the children's responses and not just be completed by the parents, as parents may be limited in their ability to characterize their children's headaches. In a study of 3461 parents and children (age 7 to 14 years), parents were accurate in reporting their child's headache frequency, but were less accurate recognizing other features associate with migraine (Kroner-Herwig et al., 2009).

Young children are also limited in their descriptive ability of their headaches and the use of children's drawings have been demonstrated to be both sensitive and specific in their diagnosis of paediatric headaches (Stafstrom et al., 2002, 2005; Wojaczynska-Stanek et al., 2008). In addition, very young children often will have additional variants of migraine such as the childhood periodic syndromes. The childhood periodic syndromes are thought to be precursors of migraine, are often first recognized as a child may not focus on the head pain, but rather on some of the abdominal symptoms (cyclic vomiting and abdominal migraine) or vertigo (benign paroxysmal vertigo of childhood). As the child ages they are better able to describe the head pain and the presence of migraine becomes more evident.

Evaluation guidelines have been developed by the collaboration of the American Academy of Neurology (AAN), Child Neurology Society, and the American Headache Society (Lewis et al., 2002). These guidelines reviewed the existing evidence for the evaluation of children with headaches and found that the neurological examination is the most critical test for identifying potential serious complications, while also confirming that the occipital location warranted further evaluation. When further evaluation is needed, a magnetic resonance imaging (MRI) study is the most sensitive test to identify structural abnormalities and should be the preferred neuroimaging test.

In addition to a complete history, general examination, and neurological examination, a comprehensive headache examination should also be performed (Linder, 2005). The comprehensive headache examination extends the neurological examination to examine for neck tenderness and stability, the stability of the temporomandibular joint, sinus and facial tenderness including peripheral nerve tenderness, and general cranial palpation. One useful test for sinus-related symptoms is Muller's sign in which the patient pressurizes their sinus and then coughs to create a brief vacuum, thus evaluating the openness of the sinuses. The applicability of this test at the bedside is very useful in dispelling any misperceptions of the headaches as sinus headaches.

As part of the history, the impact of the headache on a child's life needs to be assessed. The impact of a disease can be measured by its effect on the quality of life of the patients as well as the specific disability due to a disease. For paediatric migraine several instruments have begun to address these concerns. A review of the literature on the impact of paediatric migraine found 33 studies addressing this question and the tools used found that although the quality was inconsistent, the impact of migraine on a child's and family's lives was significant (Kernick and Campbell, 2009).

For quality of life one of the most widely administered tools for the assessment of the impact on paediatrics and adolescents' quality of life is the PedsQL 4.0 (Varni et al., 2001). This easily administered instrument address the quality of life in a disease-

independent manner. The quality of life of children with headaches can be measured at a developmentally appropriate level and has an impact similar to other chronic disease (Powers et al., 2003, 2004). With treatment this impact improves, although there is preliminary evidence of a persistent impact even after successful treatment.

Disease-specific loss of function can be persistent in many chronic diseases. Headache and migraine is unique in its episodic nature and may therefore be more variable. For children and adolescents PedMIDAS has been developed (Hershey et al., 2001, 2004). This tool can be easily administered in clinical practice and used to assess the disability of an individual patient, the need for preventative medication, and the response to treatment.

The disability and impact of paediatric migraine in tertiary clinics is clear and it is becoming apparent that this also applies to paediatric and adolescent patients in the population. Assessing this can help guide the referral to specialty centres and measure the long-term outcome.

### Comorbid conditions

The presence of additional diseases and conditions can complicate the diagnosis, management, and outcome of paediatric migraine. The common occurrence of secondary conditions that may directly contribute to headaches in children can confuse the underlying aetiology and delay the diagnosis of primary headaches while the impact of these comorbid conditions may also affect the underlying pathophysiological basis of children with migraine.

Several conditions have been demonstrated to have a comorbid relationship with migraine. These include asthma and allergic disorders (Gurkan et al., 2000; Ku et al., 2006), obesity (Hershey et al., 2009; Pinhas-Hamiel et al., 2008), epilepsy (Pellock, 2004; Piccinelli et al., 2006; Stevenson, 2006; Yamane et al., 2004), sleep disorders (Bruni et al., 1997; Gilman et al., Isik et al., 2007; 2007; Luc et al., 2006; Miller et al., 2003; Pakalnis et al., 2009), and psychological/emotional disorders (Kroner-Herwig et al., 2008; Pakalnis et al., 2007; Vannatta et al., 2008). The mechanism by which these comorbid conditions alter the expression of migraine and thus influence the underlying pathophysiology is largely unknown, but may be a consequence of the difficulty coping with multiple illnesses or may have a common pathway in brain pathology.

In adults one of the most frequently misdiagnosed headache is sinus headache (Cady and Schreiber, 2004; Schreiber et al., 2004). The presence of allergy and asthma symptoms in children may lead to the same confusion. In the screening of a large database of approximately 5000 children presenting to a tertiary headache centre, asthma was reported in 12.0% of these children. In contrast, using the same methodology to screen a tertiary asthma and allergy clinic, nearly 45.9% of these patients had recurrent headaches (Khurana Hershey et al., 2005). In comparing these two groups the patients referred primarily for a complaint of headache had the highest frequency and disability.

Head injury is another frequent event in children and adolescents. Many children can recall a significant or memorable head injury. When this occurs in a patient with a history of recurrent headache or migraine, it can often exacerbate the underlying primary headache disorder and complicate the evaluation and management and may affect the overall outcome.

With the increasing worldwide rate of obesity it has been noted that adults with migraine and obesity have a higher frequency and poorer response to treatment. This appears to also be present in adolescents.

In a multisite study of children with migraine it was found that children with a body mass index (BMI) percentile at the extremes (<5th percentile and >95th percentile) and children at risk of obesity (85th to 95th percentile) had a higher likelihood of increased frequency of headaches and disability. Intervention in the children that were obese or overweight through healthy weight control demonstrated a greater degree of improvement compared to children whose BMI remained high or increased (Hershey et al., 2009).

Sleep disturbances may increase the occurrence of migraine with sleep deprivation or altered sleep patterns triggering migraines. Furthermore, patients with migraine may also have comorbid sleep disorders. In a study of 1073 adolescents, the most frequent triggering factor for both migraine and non-migraine headaches was 'bad sleep' (Bruni et al., 2008). In a separate study, these sleep disturbances were identified as insufficient sleep (65.7%), daytime sleepiness (23.3%), difficulty falling asleep (40.6), and night waking (38%) (Gilman et al., 2007).

Psychological factors may play a complicated role in paediatric migraine that has been addressed in small studies that remain mixed in their findings (Powers et al., 2006). In a case-control designed study of 47 children (age 8–14 years), mothers perceived emotional and behavioural difficulties (Vannatta et al., 2008), while their classmates identified these same children with higher leadership and popularity (Vannatta et al., 2008). The impact of psychological factors and school stressors have a significant impact on headaches with school phobia and anxiety exacerbating headache frequency (Fujita et al., 2009).

Headache may lead to suicidal ideation. A study of 3963 adolescents in Taiwan found that 8.5% had suicidal ideation, with an increased odds ratio of 2.9 for those adolescents with migraine and 4.6 in migraine with aura (S. J. Wang et al., 2009). This was impacted by both headache frequency and disability as measured by PedMIDAS.

### Treatment

The treatment of paediatric migraine can be divided into pharmacological and biobehavioural medicine. Pharmacological treatments include both acute and preventative strategies to minimize the impact of the attacks, while biobehavioural treatment includes adherence strategies, coping skills, relaxation techniques, and healthy lifestyles. Goals of treatment should include rapid consistent treatment with a quick return to function (acute treatment), while also minimizing the frequency and impact of the migraine (preventative and biobehavioural treatment). These strategies often fail to be employed in general practice. In a study of 151 children age 10.4±3.2 years, only 30.2% were prescribed an appropriate dose of ibuprofen with only 26.5% instructed to treat the headache early (Cuvellier et al., 2007). In addition, lifestyle adjustments were recommended in less than 15% and only 8% were asked to keep a headache diary. Thus a critical component of paediatric headache management is education of the primary care providers as well as the patients and parents on the incorporation of all of these strategies.

### Acute

The goal of acute treatment of paediatric migraine should be consistent response with minimal side effects and quick return to normal function. A detailed analysis and subsequent guidelines have been reported (Lewis et al., 2004). The effective acute medications fall into two broad groups—non-steroidal anti-inflammatory

medications (NSAIDs) and triptans. The general principle is that NSAIDs (especially ibuprofen) are effective when used early in the attacks at an adequate dose (7.5–10.0 mg/kg/dose) and that triptans are effective when the NSAIDs are not completely effective, especially during the more severe attacks. Two triptans are currently approved by the US Food and Drug Administration (FDA) for children—almotriptan for ages 12 to 17 years and rizatriptan for ages 6 to 17 years.

One of the reasons for the limited number of positive studies and lack of wider US FDA approval of these medications is due to design of the studies that lead to a high placebo response rate ranging from 38% to 53% for pain relief and 17% to 26% for pain freedom at 2 h (Fernandes et al., 2008). When compared to adults, however, the overall response of the active medication in paediatric and adolescent studies was similar to the adult studies (Evers et al., 2009).

In a double-blind, placebo-controlled, three-way crossover study that included children down to age 6 (age 6–17 years old), rizatriptan was found to be consistently more effective than placebo at 2 h—74% for first treatment, 73% for second treatment versus 36% for placebo (Ahonen et al., 2006). This study used a 5 mg dose for children 20 to 39 kg and a 10 mg dose for those greater than 40 kg. Furthermore, rizatriptan was more effective at 1 h (50% and 55%) compared with placebo (29%).

Using a unique study design—a single-blind, ‘placebo challenge,’ randomized, double-blind, placebo-controlled, two-way, two-attack crossover, zolmitriptan nasal spray was studied in 248 adolescents (Lewis et al., 2007). Of the 171 patients that treated at least one attack, zolmitriptan nasal spray (5 mg) was found to be superior to placebo at 1 h with a 58.1% response for zolmitriptan compared to 43.3% for placebo. This study addressed many of the placebo response issue that had complicated previous studies, while also using a cross-over design.

A randomized, double-blind, placebo-controlled trial of almotriptan in with 866 adolescents (age 12–17 years) found a 2 h pain-relief rate that was significantly higher for all doses of almotriptan—6.25 mg (71.8%), 12.5 mg (72.9%), and 25 mg (66.7%) compared with placebo (55.3%) (Linder et al., 2008). Further analysis demonstrated superior sustained response with improvement in migraine-associated symptoms for almotriptan compared to placebo with the 12.5 mg dose associated with the most favourable response.

Adult studies have shown that combining NSAIDs with triptans is a highly effective way to improve the acute treatment of migraine (Brandes et al., 2007; Smith et al., 2005).

When acute treatment fails to relieve the headache, patients frequently visit the emergency department (Walker, 2008). A study of 432 children (2–18 years old, mean 8.9 years) visiting a paediatric emergency department found that headache was responsible for 0.8% of all the visits with respiratory disorders contributing 19.2% to the aetiology, migraines 18.5%, TTH 4.6%, post-traumatic headaches 5.5%, meningitis 4.1%, hydrocephalus 0.9%, and brain tumours 0.7% (Conicella et al., 2008). A study of 550 patients over a 12-month period, found headache to be responsible for 1.0% of the visits with primary headache representing 56.7% (9.6% migraine) and 42% as secondary headaches (Scagni and Pagliero, 2008). Viral illness contributed to 90.5% of the secondary headaches with a serious illness found in 4%. Only 40.5% of the patients received pharmacological treatment.

Treatment for children with headache in the emergency department, however, is often lacking. A Canadian study demonstrated that 44.2% received no treatment (23.3%), simple oral analgesics (with dopamine antagonist prescribed in 20.7%, opiates in 5.5%, ketorolac in 4.7%) and dihydroergotamine (DHE) in 1.0% (Richer et al., 2007). One of the most effective treatments for children in the emergency department is the combination of a dopamine antagonist (prochlorperazine) with ketorolac (Kabbouche and Linder, 2005; Kabbouche et al., 2001).

When these emergency department treatments are not successful, inpatient treatment may be necessary. In adults this has classically included the use of DHE and appears to be effective in children with 74.4% of the patients treated with DHE becoming headache free with a significant improvement in nearly all of the patients (Kabbouche et al., 2009). Nausea was the most common side effect, but otherwise the DHE was well tolerated.

Medication overuse is often a complicating factor in children with frequent headache but can be avoided with limitations in the number of times an acute medication is used. General guidelines are to limit the use of non-specific analgesics to less than two to three times per week, while limiting migraine specific agents to less than six times per month.

### Preventative

When headaches are frequent (more than once a week) or disabling (PedMIDAS score above 30—Grade III or IV), preventative treatment should be considered. The goal of preventative treatment is to reduce the headache frequency (less than one to two per month) with decrease disability (PedMIDAS less than 10) for a sustained period of time (4 to 6 months). The presence of comorbid conditions may guide the treatment of choice. No medications are currently approved by the US FDA for the prevention of paediatric headaches and the AAN practice only identified flunarizine (not available in the US) as having sufficient evidence (Lewis et al., 2004).

Agents that have been used for paediatric migraine prevention include antidepressant medications, including amitriptyline (Hershey et al., 2000); antihypertensive medications, including propranolol (Forsythe et al., 1984; Ludvigsson, 1974; Olness et al., 1987); antihistamine/antiserotonergic medications, including cyproheptadine (Levinstein, 1991); and antiepileptic medications including valproic acid (Apostol et al., 2008, 2009a, 2009b; Serdaroglu et al., 2002) and topiramate (Lakshmi et al., 2007; Lewis et al., 2009; Winner et al., 2005).

Additionally, nutraceuticals may also be effective in treating paediatric headaches. Coenzyme Q<sub>10</sub> appears to be deficient in a significant number of children and adolescents with frequent headaches (Hershey et al., 2007; Slater et al., 2011). Supplementation was noted to be associated with improvement in headache frequency in this open-labelled clinic observation study. Other agents that are also considered include butterbur—77% of children having a 50% or greater reduction in headache frequency in an open-label study (Pothmann and Danesch, 2005), riboflavin (Bruijn et al., 2010; O'Brien and Hershey, 2010), and magnesium (F. Wang et al., 2003).

### Biobehavioural

Biobehavioural therapy, or the incorporation of adherence, education, lifestyle adjustment, and coping skills, is also essential to the management of paediatric migraine (Powers and Andrasik, 2005). Educating the patient and family on the proper use of their acute and

preventative medication with a discussion about the importance of treatment and inclusion of the child in the decision-making process may greatly improve the adherence to the treatment approach. Adherence assessment has not yet been well studied in paediatric migraine, but is being recognized as an important component of the management of children with chronic or episodic disorders.

Incorporation of healthy lifestyle habits is also important to effective headache management. This includes adequate hydration with limited use of caffeine-containing beverages; a healthy, balanced diet while avoiding skipping meals; regular exercise; and sufficient sleep on a regular basis. As already discussed, sleep disturbances have begun to be studied as a significant contributor to paediatric migraine and treatment of the disturbances needs to be included in the treatment plan.

In order to attain this treatment several different approaches have recently been reported. Using telephone-assisted behavioural therapy, there was a trend to improvement in 34 adolescents after a 3- and 8-month period (Cottrell et al., 2007). Another study has begun to address the feasibility of using a CD-ROM to teach this behavioural therapy (Connelly et al., 2006).

### Tension-type headaches

TTHs are generally thought of as mild recurrent headaches. Other names for this type of headache have included muscle contraction headache, idiopathic headache, and tension headache. They can be infrequent (less than one a month), frequent (more than once a month, but not more than half the month), and chronic (more than half the month). The headache severity is usually described as mild to moderate with the location being diffuse or in a band-like pattern and have a pressing pain quality. Similar to migraine, TTH is a primary headache disorder, and secondary aetiologies should be identified and the patient should have a normal neurological examination and comprehensive headache examination. As a primary headache, the most difficult component of making the diagnosis of TTH is separating it from migraine. This is largely due to the overlapping diagnostic characteristics, especially in severity (TTH as mild to moderate, migraine as moderate to severe) and associated symptoms (the allowance of nausea, photophobia, or phonophobia in TTH, but not vomiting).

The ICHD-II (Headache Classification Subcommittee of the International Headache Society, 2004) identifies four subtypes of TTH: ICHD 2.1 infrequent episodic tension-type headache, ICHD 2.2 frequent episodic tension-type headache, ICHD 2.3 chronic tension-type headache, and ICHD 2.4 probable tension-type headache. These are further subclassified according to the presence or absence of pericranial tenderness.

### Diagnosis

Establishing a diagnosis of TTH in children is often difficult due to a lack of recognition of the headache characteristics, either due to a misunderstanding of the questions asked by the interviewer or separating the features from migraine. This may be heightened in TTH due to the lack of disease impact and disability, such that the patient and parent may not attend to these features as readily as they do for migraine.

As TTHs are often mild, the patient and parent may be vague in their descriptions with the parents unaware of the frequency of the headaches, especially if mild. Using standardized criteria such as the ICHD-II criteria, is useful in the diagnosis of paediatric

headaches and can serve to guide the interview process. Children's headache diagnosis is further complicated by the shorter duration of the headaches with spontaneous resolution, or response to rest, sleep, or behavioural therapies. Due to these issues, it may be necessary to observe the child over time and utilize diaries to identify the diagnostic characteristics.

The typical features that separate TTH from migraine are a lack of throbbing or pulsatile quality of the pain, a diffuse location, a mild severity, and lack of significant associated symptoms. Some researchers have argued that TTH and migraine are in a continuum (Cady et al., 2002), while others have argued that these are separate diseases with a broad spectrum of headaches represented by migraine (Lipton et al., 2000). Until biomarkers are available, this debate and the diagnosis of these two primary disorders will continue to have an overlapping difficulty.

### Epidemiology

In adults, TTHs are thought to be the most common type of primary headache disorder, with a lifetime prevalence ranging from 30% to 78%. Yet TTHs remain the least well studied of the primary headache disorders. This is likely due to their low severity and lack of impact on a patient's quality of life and disability.

In children, all headache disorders have been less well studied and this is especially true for TTH (reviewed by Anttila, 2006). Epidemiology rates of TTH in children have been variable and have ranged from 0.9% (Abu-Arafeh and Russell, 1994) to 73% (Barea et al., 1996), with the most frequent range reported as 10% to 25% (Anttila, 2006). Using ICHD-I criteria, TTH are reported in 9.8% of 7- to 16-year-olds in Sweden (Laurell et al., 2004) and 12% of 12-year-olds in Finland (Anttila et al., 2002a). In the study from Finland, many of the children diagnosed with TTH had migrainous features with lack of muscle tenderness in children with TTH (Anttila et al., 2002). Both of these studies demonstrated an increasing frequency of TTH in girls over boys during adolescence. As this is also seen in migraine, there remains the possibility of an overlapping evolution of the diagnosis from migraine to TTH and vice versa.

The epidemiological identification of TTH, however, is hampered by the lack of attention paid to these headache disorders, especially when infrequent. Therefore, population-based epidemiology studies may underestimate the prevalence of TTH due to a recall bias, while the inaccuracies of the recall of individual features may overestimate the misclassified TTH that should actually be considered migraine. Regardless of these limitations, both migraine and TTH are common pain problems for both children and adults.

### Treatment

Once it has been determined that a patient has TTH, a management plan needs to be developed. As is the case for most headache treatment studies in children, no large-scale treatment studies have been performed with a focus on TTH in children. For adults, several large studies that meet standard study guidelines have been performed (reviewed by Fumal and Schoenen, 2008) and the same basic principles of migraine management can be applied to TTH management—acute therapy, preventative therapy, and biobehavioural therapy with psychological intervention.

### Acute

Episodic TTH may be self-limited and may be managed with simple analgesics such as acetaminophen and NSAIDs—ibuprofen or

naproxen sodium. Both of these groups of medicines have been demonstrated to be effective in migraine in children and, by implication, may also be useful in TTH in children.

In addition, as TTH may be mild, but become frequent, the patient and family should be cautioned about the overuse of acute medication and subsequent medication overuse. This may be a major contributor to chronic daily headache. Since a mild TTH with no disability is often treated at home without or with limited medical professional intervention, this needs to be addressed at the initial use of acute medication.

When these simple analgesics are ineffective, the diagnosis should be re-evaluated and a consideration of migraine or other primary headache treatment initiated. This can include the triptans or indomethacin and may unmask an indomethacin responsive primary headache.

### Preventative

When the TTH become frequent, preventative therapies may become necessary, especially if disability occurs. This is often the trigger for parents to seek medical attention for their child. For adults, amitriptyline has been demonstrated to be useful for prophylaxis of chronic TTH (Bedsten et al., 1996; Gobel et al., 1994). The preventative treatment of TTH in children is lacking and often gets overlapped with the treatment of chronic migraine or chronic daily headache. In adults with chronic TTH, the combination of amitriptyline and cognitive therapy may be even more effective than either one by itself.

### Biobehavioural

Biobehavioural therapy includes adherence therapy, lifestyle adjustments, and specific psychological interventions including biofeedback-assisted relaxation therapy (BART) (Bussone et al., 1998) and cognitive-behavioural therapy. In a school-based study for the treatment of childhood headaches including TTH, adolescents responded well to relaxation therapies (Larsson et al., 2005). In children with TTH, biobehavioural therapy has been demonstrated to have prolonged effects over 3 years (Grazzi et al., 2001) and may be comparable to amitriptyline (Grazzi et al., 2004).

Overall, the treatment plan needs to incorporate all three components to be successful. With time, the TTH may also evolve into migraine or other primary headaches disorders and the treatment plan further adjusted (Kienbacher et al., 2006).

## Secondary headaches

Secondary headaches are frequently diagnosed in children. Oftentimes this is a misdiagnosis of a primary headache, but needs to be ruled out and treated when suspected. A thorough review of secondary headaches can be found in *The Headaches* (3rd edition; Olesen et al., 2006) or *Wolff's Headaches and Other Head Pain* (8th edition; Silberstein et al., 2008). The remainder of this chapter will highlight a few secondary headaches that can be seen in children.

### Medical-systemic causes of headache

Secondary headaches can occur as a symptom of other medical problems or to primary neurological disorders. This can include infections, metabolic disorders, renal problems, mitochondrial disorders, increased blood pressure, and haematological disorders. When a patient has a known medical condition either the condition itself or the treatment may induce headaches. It must be kept in

mind that patients with known medical problems are not protected from primary headaches and if there is not a direct cause and effect and variation with treatment, a diagnosis and management of a primary headache disorder should be considered.

### Vascular disorders

Vascular disorders can frequently have a headache as one of their symptoms (Roach and Riela, 1995). This can be attributed to ischaemia, haemorrhage, or diseases of the blood vessels including malformations, arteritis, injury to the vessels (i.e. dissection or surgical intervention), thrombosis, or genetic diseases of the blood vessels (i.e. CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leucoencephalopathy), mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes (MELAS)). These disorders for the most part are rare in children, but should be considered when other symptoms are present.

Cerebrovascular disease in children is rare occurring at a rate of 2.5/100 000. Symptoms of acute neurological changes occur at the same time of the headache. This needs to be considered on the first presentation of hemiplegic migraine, even in the setting of a family history.

Haemorrhage may be secondary to rupture of a vascular malformation or aneurysm or secondary to trauma. The presenting symptom is most often an acute severe headache ('worst headache of my life') associated with loss of consciousness, meningismus and local neurological symptoms. An underlying neurocutaneous disorder should be sought. If this diagnosis is suspected, imaging will usually show the haemorrhage. Angiography or venography may delineate the specific aetiology.

Vasculitis is being reported with increased frequency in children and adolescents but remains uncommon. Headaches occur in 40% to 70% of patients with primary central nervous system (CNS) vasculitis. It may occur in the setting of an autoimmune disorder such as systemic lupus erythematosus, polyarteritis, Wegener's granulomatosis, and Sjögren's syndrome. Although headaches may uncommonly be the initial symptom, other systemic symptoms have usually preceded the headache. The headaches may resemble either chronic TTH or migraine and usually exacerbate when the underlying autoimmune disorder worsens. Other neurological symptoms may include behavioural changes, cognitive dysfunction, seizures, and focal deficits. An MRI and magnetic resonance angiogram may show abnormalities. Cerebrospinal fluid (CSF) may be abnormal. Angiography may be required.

Emboli and thrombosis may be idiopathic or secondary trauma, coagulation disorders, autoimmune disorders, and congenital heart disease. Conditions such as moyamoya disease, fibromuscular dysplasia, arterial dissection, tumour, trauma, sickle cell anaemia, haemophilia, and dehydration may also cause secondary vascular disease.

Venous sinus thrombosis may occur in the presence of an underlying metabolic or systemic infection, a coagulation disorder, or patients who are dehydrated. The patients may present with headache, altered consciousness, lethargy, focal neurological symptoms and seizures. The neurological examination is usually abnormal and the MRI, as well as the magnetic resonance venogram, may show the thrombosed vessel and/or haemorrhage secondary to venous thrombosis. Consideration should be given to this diagnosis in the presence of a coagulopathy, systemic malignancy, and/or chemotherapy.

## Neoplasms

Intracranial tumours are the second most common type of neoplasm in children (Honig, 1982). In children younger than 15 years, the incidence is 2.4/100 000. Certain genetic syndromes such as neurofibromatosis, tuberous sclerosis, von Hippel–Lindau disease, and ataxia telangiectasis pose a greater risk for the development of neoplasms.

The fear of a brain tumour is one of the major concerns of parents bringing their children to the physician for evaluation of headache. However, the prevalence of primary headaches far outweighs the frequency of tumour-related headaches. There is a clear association between brain tumours and headaches with the majority of brain tumour having headache as one of the presenting manifestations.

The headache due to a brain tumour is the result of increased intracranial pressure due to the mass effect of the tumour or a blockage of cerebral spinal fluid drainage. In addition, the effects of the brain tumour on the surrounding tissue also induce changes in the neurological examination or neurological symptoms (Lewis et al., 2002). Other symptoms of brain tumour include seizures, ataxia, weakness, visual abnormalities, lethargy, and personality change in the majority of such patients—the course will be progressive. The neurological examination will be abnormal and the diagnosis can be confirmed by neuroimaging.

Due to the continued growth of the tumour, the headache pattern is usually chronic, progressive, with increases in frequency and severity over time. The rapidity of the growth of the tumour and the adaptability of the intracranial space to respond to this growth can modify the timing of the headache's presentation. It is frequently reported to occur in the morning due to a 'ball-valve' effect in which the CSF pressure builds in the recumbent position and is relieved by posture—the opposite of idiopathic intracranial hypertension.

## Substance-induced headache

Prescribed medications, illicit drugs, dietary compounds, and toxins can cause headaches (Silberstein et al., 1998). These substances may initiate a headache, exacerbate a pre-existing headache, or cause headache on its withdrawal. A thorough history of exposure to medications and non-medications needs to be performed and removal or alteration of these substances, if possible, may be necessary before the headache responds. Stimulants used in the treatment of attention-deficit disorder may initiate headache, especially if they are restarted at maximum dosage after not having been taken for several days to weeks. One common stimulant used in children and adults is caffeine and caffeine addiction and its withdrawal can contribute to headache and exacerbate primary headaches.

Medication overuse headache (MOH) can occur with overuse of over-the-counter analgesic medication or prescription medications. This has formerly been referred to as analgesic rebound headache. It is often associated with a gradual increase in frequency of medications that were successful or partially successful in headache treatment. These medications are typically taken at low doses or with repeated doses building to very frequent usage—up to daily. ICHD-II defines medication overuse as using prescription medications more than ten times per month or over-the-counter analgesics more than 15 times per month, increasing the likelihood of MOH. Almost all medications used for the acute treatment of migraine can potentially cause MOH. If MOH is thought to be a contributor

to the development of frequent headaches, they should be limited for 4 to 6 weeks. At that point they can be re-introduced, but at a limited frequency.

## Infectious disorders

Systemic infectious disorders or those localized to the CNS are commonly associated with headache. The presence of an elevated temperature and tachycardia alone frequently give rise to a pounding headache which is often relieved when the temperature is lowered and the infection is treated. Among the common infections seen are sinusitis, otitis media, and pharyngitis. Among the infections affecting the CNS are meningitis, aseptic meningitis, and encephalitis (Bale, 1999). Brain abscess is uncommon. It occurs more commonly in children with cyanotic congenital heart disease, open head trauma, chronic ear infections, chronic pulmonary disease, post-neurosurgical procedures, and in the immunocompromised patient.

In any CNS infection, in addition to symptoms of increased intracranial pressure or progressive neurological disease, meningismus, rash, or elevated temperature may be present. Initial evaluation should include a brain imaging procedure to rule out a mass lesion. If at all possible, this should be performed prior to any lumbar puncture.

## Conclusion

The majority of recurrent headaches in children and adolescents are primary headaches. Secondary headaches, however, occur due to systemic or CNS disease. The history and physical examination should help identify whether a headache is primary or secondary with appropriate laboratory tests and neuroimaging confirming the suspicion. Ultimately, the diagnosis of the secondary headache will be the resolution of the headache once the secondary cause has been effectively treated, while persistence of recurrent headaches without the secondary cause helps confirm the diagnosis and management of primary headaches.

## CHAPTER 32

# Persisting pain in childhood medical illness

Martha Mherekumombe and John J. Collins

### Summary

Persisting pain in the context of medical illness has been recognized recently as a global problem by the World Health Organization (WHO, 2012). Whilst the epidemiology of medical illness varies throughout the world, the general principles of pain management are applicable to most medical illnesses in children and are effective. Successful pain management for most children is contingent on the availability of the WHO model list of essential medicines for children (WHO, 2011), although regrettably not all medicines are available in every country in the world.

### Introduction

Pain is commonly experienced by children in the context of medical illness. This may be due to acute or short-lived pain related to procedures for diagnostic, treatment, or surgical interventions. Persisting pain refers to any long-term pain and medical illnesses refers to specific situations of ongoing tissue damage where there is a clear role for pharmacological treatment. Persisting pain in childhood illness implies the duration of pain is lasting beyond what would be expected from an acute injury. This latter is currently the subject of a WHO initiative to improve management of persisting pain in children due to medical illness (WHO, 2012). This chapter discusses persisting pain in the context of non-malignant disease (HIV/AIDS, cystic fibrosis, neurofibromatosis, neuromuscular disease, cerebral palsy) and confines itself to a discussion of pharmacological management. The reader is referred to other sections of this book for the issues and management of persisting pain due to other conditions and for non-pharmacological strategies for pain management.

### The pharmacological management of persisting pain in children with non-malignant illnesses

The principles of pain management in the context of paediatric medical illness are broadly applicable to most disease processes. The correct use of analgesic medicines will relieve pain in most children with persisting pain due to medical illness and relies on the following key concepts (Box 32.1):

- ♦ The availability of medicines on the WHO model list of essential medicines for children (WHO, 2011b).
- ♦ Using a two-step strategy for analgesic prescription: simple analgesics for mild pain (step 1), opioids for moderate to severe pain (step 2).
- ♦ Dosing of analgesics at regular intervals when pain is constant ('by the clock'). It is also recommended that children with persisting pain have medicines available for breakthrough pain. As there is insufficient evidence to recommend a particular opioid or route of administration for breakthrough pain in children, there is a need to make an appropriate choice of treatment modality based on clinical judgement, medicine availability, pharmacological considerations, and patient related factors.
- ♦ Using the simplest route of administration and avoiding the intramuscular route ('by the mouth'). The choice of alternative routes of administration when the oral route is not possible should be based on clinical judgement, availability, feasibility, and patient preference.
- ♦ Tailoring treatment to the individual child ('by the individual').

Among other WHO recommendations, paracetamol and ibuprofen are the medicines of choice in the first step (mild pain) and morphine is recommended as the first-line strong opioid for the treatment of persisting moderate to severe pain in children with medical illnesses. The selection of alternative opioid analgesics to morphine should be guided by considerations of safety, availability, cost, and suitability, including patient-related factors. Switching opioids and/or route of administration in children is recommended in the presence of inadequate analgesic effect with intolerable side effects. Routine rotation of opioids is not recommended (WHO, 2012).

### Opioids for the management of non-malignant pain in childhood

Data on the management of severe pain using opioids in children with non-malignant disease is limited. One retrospective review studied opioid prescription for chronic severe non-malignant pain in a multidisciplinary paediatric pain clinic. During a 12-month period, 104 patients were seen in the clinic, of which 49 received an opioid as part of their pain management; 11 received an opioid for more than 3 months, and five of these were still receiving an opioid at the end of the study period. Overall, there appeared to be better

**Box 32.1 WHO key concepts: the pain management of persisting pain in children with medical illness**

1. Using a two-step strategy for analgesic prescription, simple analgesics for mild pain (step 1), opioids for moderate to severe pain (step 2).
2. Dosing at regular intervals when pain is constant ('by the clock'). It is also recommended that children with persisting pain have medicines available for breakthrough pain.
3. Using the simplest route of administration ('by the mouth') and avoiding the intramuscular route. The choice of alternative routes of administration when the oral route is not possible should be based on clinical judgement, availability, feasibility, and patient preference.
4. Tailoring treatment to the individual child ('by the individual').

pain control and improved function in these patients while receiving opioid therapy in the context of prescription in a multidisciplinary pain clinic with a multisystem approach to pain management. More data are needed to know if such therapy is safe and beneficial on a longer-term basis (Slater et al., 2010).

### **Adjuvant analgesics for management of persisting pain in children with medical illness**

An adjuvant analgesic is a medicine that has a primary indication other than pain, but is analgesic in some painful conditions. This excludes medicines administered primarily to manage adverse effects associated with analgesics, such as laxatives and antiemetics. The WHO recently reviewed the evidence for the use of adjuvant analgesic medicines in pain management for children (WHO, 2012). The use of corticosteroids as adjuvant medicines is not recommended for the treatment of persisting pain in children with medical illnesses, nor is the use of bisphosphonates for the treatment of bone pain in children due to the low quality of evidence. Although frequently used for the management of neuropathic pain in children, it was not possible to make evidence-based recommendations for or against the use of tricyclic antidepressants (TCAs), selective serotonin reuptake inhibitors (SSRIs), or anticonvulsants as adjuvant medicines. In addition, recommendations regarding the risks or benefits of ketamine or systemic local anaesthetics as adjuvants to opioids for the treatment of neuropathic pain in children, or for the use of benzodiazepines and/or baclofen as adjuvants in the management of pain associated with muscle spasm and spasticity, could not be made based on the current literature. The quality of current evidence, and risks and benefits of different treatments are summarized in the WHO document, and the need for further analgesic research in children with persistent pain and medical illness to establish the role of these medicines in paediatric pain treatment is emphasized (WHO, 2012).

### **WHO health system recommendations for a global strategy to improve pain management in children**

In an effort to ensure the universal application of the general principles and clinical recommendations, the WHO also makes health system recommendations acknowledging that lack of access to the correct treatment for persisting pain is often related to issues in the

health system (WHO, 2012). It recommends the education of health professionals in the standardized management of persisting pain in children with medical illnesses and in the handling of the necessary medicines, including opioid analgesics. Further, health professionals should be allowed to handle opioids within their scope of practice or professional role based on their general professional licence without any additional licensing requirements. Individual countries may consider, subject to their situation, allowing other professions to diagnose, prescribe, administer, and/or dispense opioids for reasons of flexibility, efficiency, increased coverage of services, and/or improved quality of care. The conditions under which such permission is granted would be based on the demonstration of competence, sufficient training, and personal accountability for professional performance (WHO, 2012).

### **Human immunodeficiency virus and acquired immunodeficiency syndrome**

Human immunodeficiency virus (HIV) causes immunosuppression by infecting the immune system, in particular CD4 (cluster of differentiation 4, a glycoprotein expressed on the surface of T helper cells, monocytes, macrophages, and dendritic cells) lymphocytes. Immunosuppression from the viraemia results in variable disease manifestations and disease progression (Luzuriaga and Sullivan, 1998).

A growing number of children and young adults in the world are infected with HIV, with the majority of these in developing countries. Approximately 3.4 million children under the age of 15 are living with HIV worldwide, and there were an estimated 390 000 newly infected children in 2010 (UNAIDS, 2011). The majority of these children live in sub-Saharan Africa where skilled clinicians, medications, and technology limit the provision of optimal care (De Baets et al., 2007). In 2010 the estimated number of children with acquired immunodeficiency disease (AIDS) who died in Sub-Saharan Africa was 230 000, 14 000 in South and South East Asia compared to less than 100 in North America, and Western and Central Europe (UNAIDS, 2011). The introduction of antiretroviral medication has dramatically changed the course of HIV and children are surviving longer. In the absence of antiretroviral therapy (ART), HIV disease in children is more aggressive, with a significant proportion of children presenting with severe disease. The rate of ART use in children under 15 years in developing countries as estimated by WHO in 2010 was 23%, with between 3% to 29% in Africa (WHO, 2011a). Without ART paediatric HIV is usually more aggressive and most of the children die before the age of 5 years (WHO, 2011a).

Effective pain management is also hindered by limited availability of opioids in developing countries. One study conducted in Africa showed approximately half of the children dying of AIDS received no analgesia (De Baets et al., 2007). It has been hypothesized that pain may be a unique manifestation of HIV and report of pain has been associated with a higher mortality (Gaughan et al., 2002). Effective pain management could also be hindered by potential drug interactions, and difficulties in differentiating ongoing disease and treatment side effects (Strafford et al., 1991).

### **Prevalence of pain in children with HIV/AIDS**

Pain in children with HIV is highly prevalent (Gray et al., 2010) but is commonly unrecognized, inadequately treated, and not prioritized (Norval et al., 2006). Earlier in the course of HIV, pain can be transient in nature (Oleske, 2007), but as HIV progresses and the CD4 cell count decreases, pain can be severe (AIDSinfo, 2008). With

the fall in the CD4 cell count, children with progressive disease have more pain, which can become chronic and severe (De Baets et al., 2007; Gaughan et al., 2002; Lolekha et al., 2004).

The prevalence of pain in children with HIV and AIDS is uncertain due to limited literature reports and few studies specifically related to in HIV-related paediatric pain. Reported prevalence of pain in children ranges from 20% (Gaughan et al., 2002) to 60% (Hirschfeld et al., 1996). Lolekha's cross-sectional study of a paediatric outpatient population found 44% of children with HIV complained of pain and 6.6% of these children had pain lasting more than 3 months and occurring twice or more per week (Lolekha et al., 2004). A higher incidence of pain (67%) with associated sleep disturbance has been reported in younger children (67%) (Hirschfeld et al., 1996). Serchuck et al also reported a higher incidence of pain in young children, and in girls (Serchuck et al., 2010). Gender differences are thought to be influenced by communication skills and cultural bias (Gaughan et al., 2002). Overall, the prevalence of pain in children with HIV/AIDS is comparable to that of paediatric cancer pain (between 37% to 78%; Hirschfeld et al., 1996).

Although pain is a frequent symptom, it unfortunately often continues to be poorly treated (Yaster and Schechter, 1996). Some of the reasons include: lack of confidence among health care professionals in assessing and managing pain in children and misconceptions surrounding opioid use in children (AIDSinfo, 2008). Persisting pain can be also associated with increased mortality, a decreased quality of life (AIDSinfo, 2008), and increase in hospital admissions (Josephs et al., 2010).

### Causes of pain in HIV/AIDS

HIV/AIDS pain is multifactorial and can arise from: complications of the disease (e.g. infections, inflammation, neoplasms), adverse drug reactions, and compromised immune status. Pain may be exacerbated by: psychological factors such as stress, clinical depression, anxiety, and fear; greater socioeconomic stresses (Serchuck et al., 2010); and also by poor nutritional status (AIDSinfo, 2008; Berg et al., 2009; De Baets et al., 2007; Gaughan et al., 2002; Hirschfeld et al., 1996; Serchuck et al., 2010).

Disease-related pain can affect many organs, predominately the gastrointestinal, neurological, pulmonary, and dermatological systems (AIDSinfo, 2008; Strafford et al., 1991). The most frequent cause of pain in children with HIV was gastrointestinal or limb pain (Hirschfeld et al., 1996). Other causes of somatic pain include painful disorders of the skin, connective tissue, muscle, bone, and visceral pain. Somatic pain tends to be well localized, sharp, and acute whilst visceral pain is less localized and is often described as deep, dull, aching, gnawing or spasmodic pain (Amery et al., 2009). More generalized bodily pain, headache, chest or neuropathic pain can also occur. A survey of ambulatory adult patients with HIV in the US reported somatic pain in 45% of cases, visceral pain in 15%, neuropathic pain in 19%, and in 4% of cases the causes of pain were unknown (Hewitt et al., 1997).

### Gastrointestinal pain in children with HIV/AIDS

Immunosuppression causing infection and consequent pain can manifest in any part of the gastrointestinal system. Pain can result from oropharyngeal candidiasis, dental caries, gingivitis, aphthous ulcers, herpetic stomatitis and oesophagitis from candida, cytomegalovirus (CMV), herpes simplex virus (HSV), or mycobacterium (New York State Department of Health AIDS Institute, 2001; Wilcox,

2010; Yaster and Schechter, 1996; Yogeve, 2011). Candida oesophagitis is a common problem and risk factors for developing it include prior oral candidiasis, a low CD4 count, and antibiotic use. Pain can manifest as odynophagia (painful swallowing) or retrosternal pain.

Infectious gastroenteritis from bacteria, parasites, viruses, or fungal agents can cause small and large bowel enteritis and severe abdominal pain (Wilcox, 2010). Atypical infections such as *Mycobacterium avium-intracellulare* (MAI) can cause abdominal pain, usually related to the accompanying lymphadenopathy (Wilcox, 2010). Patients with a CD4 count less than 100/microlitre are more susceptible to CMV, fungi, *Mycobacterium avium* complex (MAC), and unusual protozoa infections. CMV infection can cause pain through gastritis, a focal ulcer, gastric outlet obstruction, or gastric mass. It can also cause enteritis, small and large bowel perforation, colitis, appendicitis, hepatitis, cholecystitis, cholangitis, and pancreatitis. *Cryptosporidium* causes gastritis, gastric outlet obstruction, small bowel enteritis, appendicitis, cholecystitis and hepatitis. Conversely, patients with a CD4 count greater than 400/microlitre are more likely to have common bacterial infections or neoplasia (Wilcox, 2010).

Another rare cause of abdominal pain is gastrointestinal lymphoma (Yaster and Schechter, 1996) which may present as a mass causing obstruction, hepatic, splenic, or mesenteric infiltration (New York State Department of Health AIDS Institute, 2001; Wilcox 2010; Yogeve, 2011).

Nucleoside reverse transcriptase inhibitors (NRTIs) used in therapy can cause mitochondrial toxicity, hepatic steatosis, and abdominal pain, and there are limited reported cases in children (McComsey and Leonard, 2004). Complications from ART (didanosine, or lamivudine) include pancreatitis with or without abdominal pain and hepatitis.

### Neuropathic pain in children with HIV/AIDS

The nervous system is major target for HIV infection, which can affect both the central and the peripheral nervous systems. The nervous system can be affected in multiple ways: as a direct consequence of opportunistic infections or malignancies occurring because of immunosuppression, from treatment-related neurotoxic effects, or systemic complications of HIV on brain function (Dobalian et al., 2004). Possible HIV-related immunological mechanisms include antigen-antibody immune complex deposition in blood vessels, causing a vasculitis in small, medium, and large vessels. Evidence supporting this includes the demonstration of HIV p24 antigen in endoneurial blood vessels, HIV replication in nerve biopsies, and the presence of HIV in cultures of nerve tissue (Brinley et al., 2001; Epstein et al., 1986).

### Peripheral neuropathy

Peripheral neuropathy is reported to occur in about 13% to 34% of children with HIV/AIDS (AIDSinfo, 2011; Araujo et al., 2000). Approximately 34% of children in early or later stages of HIV report symptoms and signs of peripheral neuropathy in the absence of potential neurotoxic ARV drugs (Serchuck et al., 2010; Van Dyke et al., 2008). However, there is a higher prevalence of peripheral neuropathy in children with encephalopathy and symptomatic AIDS. Peripheral neuropathy in children is often not as severe, frequent, or debilitating as that which occurs in adults (Araujo et al., 2000; Floeter et al., 1997). It is unclear whether the peripheral nervous system of children is more resilient to neuropathic insults associated with HIV infection or whether few reports reflects an under diagnosis of peripheral neuropathy in this patient group (Floeter et al., 1997).

The incidence of ART-associated neuropathy is 0.1% with use of stavudine, lamivudine, and nevirapine (AIDSinfo, 2011). The toxicity of non-reverse transcriptase inhibitor (NRTI) therapy is thought to result from mitochondrial toxicity resulting in peripheral neuropathy, myopathy, lactic acidosis, hepatitis, hepatitis steatosis, cardiomyopathy and lipoatrophy/lipodystrophy. Not all children on combination ART, which includes an NRTI, develop peripheral neuropathy (Araujo et al., 2000; Floeter et al., 1997). HIV-positive adult Caucasian patients who have the mitochondrial haplo-group T have an increased risk of peripheral neuropathy (Hulgan et al., 2005; Van Dyke et al., 2008). Van Dyke and colleagues postulated that the mitochondrial DNA polymorphism that predisposes to NRTI-induced mitochondrial toxicity is uncommon in children from an African American or Hispanic background (Van Dyke et al., 2008). Modest rates of toxicity have also been observed in younger children although not fully defined in paediatrics.

Neuropathic pain predominately occurs in the distal lower limbs, particularly in the feet (Araujo et al., 2000; Floeter et al., 1997). The pain is usually described as aching, burning, or painful numbness (AIDSinfo, 2011). Some experience hyperalgesia and allodynia. Paradoxical hyperalgesia in association with escalating drug requirements has been reported in children undergoing prolonged intensive and invasive care (AIDSinfo, 2011; Gray et al., 2010). However, neuropathic pain can be fluctuating in nature and may not interfere with daily activities. Chronic sensory symptoms predominate, with bilateral and distal pain and paraesthesia, similar to reports in adults (Araujo et al., 2000).

### Headache in children with HIV/AIDS

Headache in HIV/AIDS can result from meningitis or meningoencephalitis opportunistic infections. Bacterial meningitis commonly presents with headache (Gumbo et al., 2002). Other causes of headache include sinusitis, central nervous system (CNS) lymphoma, viral encephalopathy, and rarely toxoplasmosis, and *Cryptococcus neoformans*. Opportunistic infections from toxoplasmosis, and CMV are uncommon in children, as infection is usually from reactivation of a previously acquired infection.

Although meningoencephalitis from *Cryptococcus neoformans* is rare in children living with AIDS compared to adult patients, there may be an increasing number of African children affected (Gumbo et al., 2002). The other causes of headache include complications of ART such as zidovudine, causing an adverse reaction. Tension headaches and migraine are reported in adults but the frequency in children is unknown. Dihydroergotamine or ergotamine should not be co-administered with protease inhibitors as this may cause ergot toxicity resulting in nausea, vomiting, and sustained vasoconstriction with local tissue hypoxia and ischemic injury. Children with HIV/AIDS can develop spasticity and rigidity due to CNS complications of infection causing considerable pain and immobility. Management of this pain involves a multidisciplinary approach help improve comfort and mobility of these patients (AIDSinfo, 2011).

### Musculoskeletal pain in children with HIV/AIDS

Bone pain in children with HIV/AIDS can be due to multiple causes that include: osteopenia as a result of bone loss and altered bone metabolism, cancer, and infections such as osteomyelitis or septic arthritis. Decreased bone mineral density is seen in children with HIV/AIDS (Fortuny et al., 2008), the pathogenesis of which is likely to be multifactorial including mineral and vitamin deficiency.

Bisphosphonates have been used to treat this type of pain and should be considered despite limited use in ARV treated HIV-infected children. Another bone problem seen in children is avascular necrosis or osteonecrosis presenting as hip pain (McComsey and Leonard, 2004). When bone pain occurs, the recommended first-line therapy is generally a non-steroidal anti-inflammatory (NSAID) provided there are no contraindications to its use.

Idiopathic polymyositis, myositis secondary to zidovudine (AZT) toxicity, and infectious pyomyositis can cause muscular pain in HIV-infected children (Lane, 1998). Muscular pain from AZT may occur as a result of an idiosyncratic reaction causing muscle weakness and elevation of muscle enzymes and can occur at all CD4 levels. Discontinuing or reducing AZT dose may reduce pain severity.

### Procedural pain and its impact in children with HIV/AIDS

Children with HIV/AIDS may experience many painful procedures such as venepuncture, bone marrow aspirate, lumbar puncture, or nasogastric tube insertion. An early report documented a total of 193 painful procedures in 22 children with AIDS (Strafford et al., 1991). The heightened pain experience from repeated painful procedures may contribute to a higher pain report in younger children (Serchuck et al., 2010). Procedural pain management is essential to minimize the experience of pain. Comprehensive guidelines are available which outline pharmacological and non-pharmacological approaches to common procedures, including preprocedure preparation (Amery et al., 2009; Schiff et al., 2001). (Additional information related to procedural pain management is included in Chapter 18 (Palmer and Babl), Chapter 19 (Taddio), and Chapter 47 (Zempsky) in this volume.)

### Special considerations for pain management in children with HIV/AIDS

Management of HIV/AIDS-related pain may be complex. It is important to recognize pain, assess its severity, and develop treatment goals for managing pain in the context to the HIV symptomatology (New York State Department of Health AIDS Institute, 2001). The availability of medications also has an impact on pain management. Poorly controlled HIV-related pain can affect a child's quality of life, interfering with activity and sleep (AIDSinfo, 2008).

Treating pain in HIV/AIDS requires a multimodal approach. Diagnosing and treating the cause of pain is vital, particularly as lowering the viral load could contribute to an improved response to analgesics (AIDSinfo, 2008). The goals of treatment should also be focused on reducing the incidence and severity of treatment-related pain. Age-appropriate pain severity measurement scales should be used and implementation of the principles of pain management as recently outlined by the WHO (WHO, 2012).

Generally, mild pain is treated with simple analgesia such as paracetamol and NSAIDs. However, NSAIDs should be used with caution as they may exacerbate bone marrow suppression and worsen gastrointestinal symptoms in patients with HIV and have potential drug-drug interactions with ARV (Gray et al., 2010).

Protease inhibitors (PIs), NNRTI or NRTIs can have significant drug interactions with analgesics, including buprenorphine, codeine, dextropropoxyphene, diamorphine, fentanyl, mefenamic acid, pethidine, tramadol, and ketamine. The simultaneous use of these medications may result in increased plasma drug concentrations, toxicity, or relative overdose of the pain medications. These interactions can be managed by altering the drug dosage or timing

of administration as well as therapeutic drug monitoring (TDM). For example, cautious use of methadone is employed in patients on PIs and NNRTIs as these drugs can induce the metabolism of methadone and lead to withdrawal symptoms. Dosing of methadone therefore need to be increased whilst on these ARV. Conversely, methadone toxicity has been reported with the discontinuation of PIs or NNRTIs (AIDSinfo, 2008).

In addition to this, the hepatic isoenzyme changes induced by these pain medications can alter PI or NNRTI pharmacokinetics (AIDSinfo, 2008). Conservative dosing is therefore recommended, with titration against individual response. Dosing guidelines exist for adults for antiretroviral drug interactions (Ammann, 2009) and interactions can be managed by altering the drug dosage or timing of administration as well as TDM. However, there is no universal rule for ARV dose calculation in children that can be considered accurate under all circumstances. Body weight is the most accessible and widely used metric, but is also the mostly likely to result in inaccurate dosing. Body surface area (BSA) is recommended as it more closely meets the efficacy and safety requirements for infants and children (Norval et al., 2006). However, as BSA does not take height into account, dosing based on the BSA should be used with caution in children with malnutrition. Careful monitoring of organ function through appropriate laboratory diagnostic tests, a patient's clinical status, weight gain, increased growth and development, decreased opportunistic infections, increased CD4 counts, and decreased viral loads can be used to confirm efficacy of the ART (Norval et al., 2006).

### Special considerations for pharmacotherapy in HIV/AIDS

Excessive activation of the N-methyl-D-aspartate (NMDA) receptor occurs in the presence of gp120, a protein found on the outer envelope of HIV (AIDSinfo, 2008). It is thought that this may contribute to increased pain severity potentially requiring escalating opioid and sedative requirements. Both dextromethorphan and ketamine block the NMDA receptor, but their use can be limited by an unfavourable side effect profile. Ketamine has anecdotally been associated with severe cardiac rhythm disturbance, electrolyte abnormalities, and even cardiac arrest in children with advanced HIV and AIDS (AIDSinfo, 2008). Adult literature suggests that methadone administration may be associated with lower CD4 cell count and CD4/CD8 cell ratios and *in vitro* studies also suggest an increase in HIV replication in human blood monocyte-derived macrophages exposed to methadone (AIDSinfo, 2008).

Myopathic pain is managed by firstly addressing the underlying cause, decreasing inflammation, and maximizing ART. Neuropathic pain and peripheral neuropathy due to medication is managed by stopping medications that produce neuropathy, and using analgesics as per the WHO recommendations (WHO, 2012). Neuropathic pain may also be managed with  $\gamma$ -aminobutyric acid agonists (GABA) such as baclofen, ART, NMDA receptor blockade, and anticonvulsants (AIDSinfo, 2008). Abdominal pain from inflammatory processes such as pancreatitis, infection, gall bladder and biliary tract disease, malabsorption syndromes, tumours, and medication side effects can all cause persisting pain in children with HIV/AIDS. Mouth pain from aphthous ulcers and dysphagia are managed by using mouth washes, a soft brush, having soft food, and appropriate analgesia. Candidiasis should be treated with antifungals such as miconazole, fluconazole, and topical anaesthetics for local pain relief. Aphthous ulcers have also been managed with prednisolone and dexamethasone mouth washes.

### Case example: human immunodeficiency virus and acquired immunodeficiency syndrome

Moses is a 4-year-old with AIDS whose parents had recently died from the same diagnosis. He was admitted to hospital in Africa with vomiting, diarrhoea, and pain. He was noted to have mouth ulcers, severe oral thrush, a cough, and noted to be underweight with signs of malnutrition, and clinically dehydrated. He was distressed and in severe pain, but unable to localize the pain. His initial management included oral morphine (which he vomited), intravenous fluids, antibiotics, and topical oral antifungals. His pain worsened and his hospital had access to an intravenous morphine preparation, as recommended by the WHO model list of essential medicines for children (WHO, 2011b). A regular schedule of subcutaneous morphine was started for the management of constant severe pain. His pain severity decreased and eventually his pain was well managed with a regular schedule of oral morphine once his vomiting stopped. Further investigations showed he also had tuberculosis (TB) and anti-TB therapy was commenced.

## Cystic fibrosis

Cystic fibrosis (CF) is an inherited multisystem disorder, and the primary defect relates to dysfunction of the cystic fibrosis transmembrane conductance regulator protein (CFTR). CF is characterized by obstruction and infection of airways and by maldigestion and its consequences. As a result, CF is the major cause of severe chronic lung disease in children, and of most cases of exocrine pancreatic insufficiency in early life (Egan, 2011). Due to the wide array of presenting symptoms and complications, CF enters the differential diagnosis of many paediatric conditions (Egan, 2011). CF is the most common life-limiting recessive genetic trait among white people, with a prevalence of approximately 1/3500 live births in northern Europe, North America, and Australia and New Zealand. The prognosis for children living with CF has improved dramatically over the last few decades. This is due to several factors including improved nutrition and improved treatment of respiratory infections. Notwithstanding this improvement in prognosis, this illness is still associated with significant morbidity, but there has been little evaluation of the extent and impact of pain on children with CF.

### Pain in cystic fibrosis

Recognition that pain is a common symptom in children with CF was first established in the 1990s. A retrospective chart review at a tertiary care hospital was conducted summarizing the end-of-life care of US patients more than 5 years of age and dying from CF (Robinson et al., 1997). Twenty-five per cent of these patients had been receiving opioids for the treatment of chronic headache and/or chest pain for more than their last 3 months of life. When opioids were used for the treatment of breathlessness and/or chest pain, the proportion increased to 86%. When pain was present, it was described as 'serious' pain with chest, head, extremity, abdomen, and back being the more common locations.

The incidence of chronic pain in children with CF increases sharply in the last 6 months of life (Ravilly et al., 1996). Headaches (55% of patients) and chest pain (65%) were frequently reported, although back pain (19%), abdominal pain (19%), and limb pain

(16%) were also common. In patients with headache, the main aetiologies were hypercarbia or hypoxia, migraine, and sinusitis. The majority of chest pain was musculoskeletal, with pleuritis, pneumothorax, and rib fracture also reported.

A recent comparative study of children and adults with CF examined the prevalence of pain in CF and the consequences to activities of daily living (Sermet-Gaudelus et al., 2009). The study included 73 children (1–18 years) and 110 adults (18–52 years); 59% of the children and 89% of the adults reported at least one episode of pain during the previous month. Pain was significantly more intense and lasted significantly longer among adults, but incidence did not differ significantly between the two populations, and was not related to the severity of CF. In this study the most prevalent locations were the abdomen for children, and the back, head, and chest for adults. Although pain significantly limited physical activity, only 15% of patients reported that it caused absenteeism, and 27% reported that it negatively affected their family life. The mean intensity of greatest pain during the past month, rated on a 0 to 10 visual analogue scale was 4.9 (2) (mean [standard deviation]) for children and 6 (2) for adults. Only 40% and 50%, respectively, of those with pain reported the use of analgesic treatment, mainly paracetamol. At least one episode of procedural pain during the previous month was reported by 85% of children and 78% of adults. This study demonstrates the high incidence of undertreated pain in CF patients throughout their lives and indicates the need for a thorough assessment of pain in children with CF.

Reported interventions for pain in CF have included a variety of non-pharmacological and pharmacological therapies (Ravilly et al., 1996). Forty-one patients (53%) had pain severe enough to require opioid treatment, and ten patients (13%) received opioids for more than 3 months. In eight patients with more severe pain, regional analgesia was found to be particularly effective (Ravilly et al., 1996).

#### Case example: cystic fibrosis

A 14-year-old adolescent with CF was admitted to hospital with severe left-sided chest pain exacerbated by deep inspiration. A chest X-ray revealed a fracture of the right anterior seventh rib and associated osteopenia. The patient was admitted to hospital for analgesia and chest physiotherapy. Analgesia consisted of intravenous opioid analgesia self-administered via a patient-controlled analgesia (PCA) pump through a central venous access device. The young patient was encouraged to administer the opioid prior to chest physiotherapy and instructed to support his chest wall when coughing. A TENS unit was used and gave improved analgesia. Osteoclast inhibitor therapy was commenced, following endocrinology review, to correct the osteopenia and reduce the chance of spontaneous fracture in the future. This patient was discharged home 2 weeks later with a regular schedule of oral analgesia for management of his persisting pain.

## Neurofibromatoses

Neurofibromatoses are autosomal dominant disorders that cause tumours to grow on nerves and are associated with other abnormalities such as skin changes and bone deformities. There are specific diagnostic criteria for neurofibromatosis type 1 (NF1)

and neurofibromatosis 2 (NF2; Sahin, 2011). NF1 is more common and has a better prognosis with a lower incidence of CNS tumours than NF2, but may still be associated with significant morbidity.

### Pain in neurofibromatosis

Neurofibromas typically involve the skin, but may also be situated along peripheral nerves and blood vessels or within viscera, and can produce pain in children (Sahin, 2011). The lesions characteristically appear during adolescence as small rubbery lesions with a slight discolouration of the overlying skin. Neurofibromas may be associated with swelling and local pain ('pins and needles' or 'shooting' pain) and dysaesthesia in the nerve distribution. Plexiform neurofibromas are often present at birth and frequently located in the orbital or temporal region of the face, result from diffuse thickening of nerve trunks (Sahin, 2011). Plexiform neurofibromas may produce overgrowth of an extremity and the deformity of the corresponding bone may cause pain.

A neurofibroma occasionally differentiates into a malignant nerve cell tumour and the incidence of pheochromocytoma, rhabdomyosarcoma, leukaemia, and Wilms' tumour is higher than the general population (Sahin, 2011). The possibility of a malignant change in a neurofibroma should be considered in the patient with pain which is persisting despite analgesic treatment.

Scoliosis is a common complication found in 10% of patients with neurofibromatosis (Sahin, 2011), and this skeletal abnormality may also be a source of pain. In addition, pathological fracture is occasionally associated with pseudoarthrosis, and should be considered in this setting if pain is of sudden onset, severe, and persisting.

#### Case example: neurofibromatosis

A 16-year-old boy presented to the paediatric pain clinic with neurofibromatosis which was diagnosed at the age of 10 years. He presented with intermittent 'sharp, shooting' pain in his arm and this followed a C5, C6 nerve distribution. His imaging studies demonstrated multiple neurofibromas along C5 and C6 nerves, but none suggestive of malignant change. Initially well controlled on a combination of simple analgesics and gabapentin as a treatment for neuropathic pain, his pain escalated over several months to become severe, constant, and precluded sleep. This change necessitated an increase in his analgesia to include an opioid given on a regular basis and the continuation of the gabapentin. A nerve biopsy was performed which diagnosed a peripheral nerve sheath tumour. Despite treatment with chemotherapy, the tumour progressed in size and caused further pain necessitating the parenteral administration of an opioid and referral for palliative care.

## Neuromuscular diseases

Neuromuscular diseases are disorders of the motor unit, which consists of the motor neuron, its axon, the neuromuscular junction, and the muscle fibres innervated by the motor neuron. Paediatric neuromuscular conditions that may be associated with pain include: developmental disorders of muscle (e.g. nemaline and central core disease), muscular dystrophies (e.g. Duchenne's), spinal muscular atrophies, and Guillain-Barré syndrome (GBS).

### Pain in neuromuscular disorders
